

1 Triangulating the Square and Squaring the Triangle: 2 Quadtrees and Delaunay Triangulations are Equivalent*

3 *Maarten Löffler*[†] *Wolfgang Mulzer*[‡]

4 Abstract

5 We show that Delaunay triangulations and compressed quadtrees are equivalent structures. More precisely,
6 we give two algorithms: the first computes a compressed quadtree for a planar point set, given the Delaunay
7 triangulation; the second finds the Delaunay triangulation, given a compressed quadtree. Both algorithms
8 run in deterministic linear time on a pointer machine. Our work builds on and extends previous results by
9 Krzmaric and Levcopolous [38] and Buchin and Mulzer [9]. Our main tool for the second algorithm is the
10 well-separated pair decomposition (WSPD) [12], a structure that has been used previously to find Euclidean
11 minimum spanning trees in higher dimensions [26]. We show that knowing the WSPD (and a quadtree)
12 suffices to compute a planar Euclidean minimum spanning tree (EMST) in *linear* time. With the EMST at
13 hand, we can find the Delaunay triangulation in linear time [20].

14 As a corollary, we obtain deterministic versions of many previous algorithms related to Delaunay trian-
15 gulations, such as splitting planar Delaunay triangulations [18, 19], preprocessing imprecise points for faster
16 Delaunay computation [8, 40], and transdichotomous Delaunay triangulations [9, 14, 15].

17 1 Introduction

18 Delaunay triangulations and quadtrees are among the oldest and best-studied notions in compu-
19 tational geometry [3, 6, 24, 28, 42, 43, 45, 47], captivating the attention of researchers for almost four

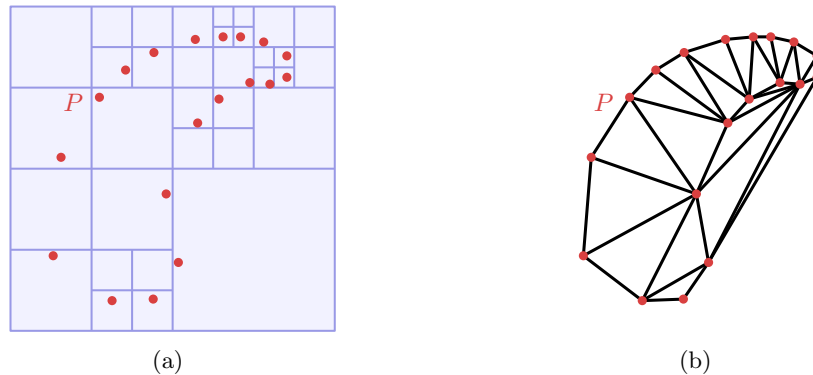

Fig. 1: A planar point set P , and a quadtree (a) and a Delaunay triangulation (b) on it.

1 decades. Both are proximity structures on planar point sets; Figure 1 shows a simple example of
 2 these structures. Here, we will demonstrate that they are, in fact, equivalent in a very strong sense.
 3 Specifically, we describe two algorithms. The first computes a suitable quadtree for P , given the
 4 Delaunay triangulation $DT(P)$. This algorithm closely follows a previous result by Krznaric and
 5 Levcopoulos [38], who solve this problem in a stronger model of computation. Our contribution
 6 lies in adapting their algorithm to the real RAM/pointer machine model.[□] The second algorithm,
 7 which is the main focus of this paper, goes in the other direction and computes $DT(P)$, assuming
 8 that a suitable quadtree for P is at hand.

9 The connection between quadtrees and Delaunay triangulations was first discovered and fruit-
 10 fully applied by Buchin and Mulzer [9] (see also [8]). While their approach is to use a hierarchy
 11 of quadtrees for faster conflict location in a randomized incremental construction of $DT(P)$, we
 12 pursue a strategy similar to the one by Löffler and Snoeyink [40]: we use the additional infor-
 13 mation to find a connected subgraph of $DT(P)$, from which $DT(P)$ can be computed in linear
 14 deterministic time [20]. As in Löffler and Snoeyink [40], our subgraph of choice is the *Euclidean*
 15 *minimum spanning tree* (EMST) for P , $emst(P)$ [26]. The connection between quadtrees and EM-
 16 STs is well known: initially, quadtrees were used to obtain fast approximations to $emst(P)$ in high
 17 dimensions [11, 49]. Developing these ideas further, several algorithms were found that use the
 18 *well-separated pair decomposition* (WSPD) [12], or a variant thereof, to reduce EMST computation
 19 to solving the *bichromatic closest pair* problem. In that problem, we are given two point sets R
 20 and B , and we look for a pair $(r, b) \in R \times B$ that minimizes the distance $|rb|$ [1, 11, 39, 51]. Given a
 21 quadtree for P , a WSPD for P can be found in linear time [8, 12, 13, 33]. EMST algorithms based
 22 on bichromatic closest pairs constitute the fastest known solutions in higher dimensions. Our ap-
 23 proach is quite similar, but we focus exclusively on the plane. We use the quadtree and WSPDs
 24 to obtain a sequence of bichromatic closest pair problems, which then yield a sparse supergraph of
 25 the EMST. There are several issues: we need to ensure that the bichromatic closest pair problems
 26 have total linear size and can be solved in linear time, and we also need to extract the EMST from
 27 the supergraph in linear time. In this paper we show how to do this using the structure of the
 28 quadtree, combined with a partition of the point set according to angular segments similar to Yao’s
 29 technique [51].

30 1.1 Applications

31 Our two algorithms have several implications for derandomizing recent algorithms related to DTs.
 32 First, we mention *hereditary* computation of DTs. Chazelle *et al.* [18] show how to *split* a Delaunay
 33 triangulation in linear expected time (see also [19]). That is, given $DT(P \cup Q)$, they describe a
 34 randomized algorithm to find $DT(P)$ and $DT(Q)$ in expected time $O(|P| + |Q|)$. Knowing that DTs
 35 and quadtrees are equivalent, this result becomes almost obvious, as quadtrees are easily split in
 36 linear time. More importantly, our new algorithm achieves linear *worst-case* running time. Ailon
 37 *et al.* [2] use hereditary DTs for *self-improving algorithms* [2]. Together with the ε -net construction
 38 by Pyrga and Ray [44] (see [2, Appendix A]), our result yields a deterministic version of their
 39 algorithm for point sets generated by a random source (the inputs are probabilistic, but not the
 40 algorithm).

41 Eppstein *et al.* [27] introduce the skip-quadtree and show how to turn a (compressed) quadtree
 42 into a skip-quadtree in linear time. Buchin and Mulzer [9] use a (randomized) skip-quadtree to

[□] Refer to Appendix A for a description of different computational models.

Fig. 2: We show which can be computed from which in linear time. The black arrows depict known linear time deterministic algorithms that work in the pointer machine/real RAM model. The red arrows depict our new results. Furthermore, for reference, we also show known randomized linear time algorithms (in green) and known deterministic linear time algorithms that work in a weaker model of computation (in blue).

1 find the DT in linear expected time. This yields several improved results about computing DTs.
 2 Most notably, they show that in the *transdichotomous* setting [14, 15, 29], computing DTs is no
 3 harder than sorting the points (according to some special order). Here, we show how to go directly
 4 from a quadtree to a DT, without skip-quadrees or randomness. This gives the first *deterministic*
 5 *transdichotomous* reduction from DTs to sorting.

6 Buchin *et al.* [8] use both hereditary DTs and the connection between skip-quadrees and DTs
 7 to simplify and generalize an algorithm by Löffler and Snoeyink [40] to preprocess imprecise points
 8 for Delaunay triangulation in linear expected time (see also Devillers [25] for another simplified, but
 9 not worst-case optimal, solution). Löffler and Snoeyink’s original algorithm is deterministic, and
 10 the derandomized version of the Buchin *et al.* algorithm proceeds in a very similar spirit. However,
 11 we now have an optimal deterministic solution for the generalized problem as well.

12 In Figure 2, we show a graphical representation of different proximity structures on planar point
 13 sets. The arrows show which structures can be computed from which in linear deterministic time
 14 on a pointer machine, before and after this paper. Please realize that there are several subtleties of
 15 different algorithms and their interactions that are hard to show in a diagram, it is included purely
 16 as illustration of the impact of our results.

17 1.2 Organization of this paper

18 The main result of our paper is an algorithm to compute a minimum spanning tree of a set of
 19 points from a given compressed quadtree. However, before we can describe this result in Section 4,
 20 we need to establish the necessary tools; to this end we review several known concepts in Section 2
 21 and prove some related technical lemmas in Section 3. In Section 5, we describe the algorithm to
 22 compute a quadtree when given the Delaunay triangulation; this is an adaptation of the algorithm
 23 by Krznaric and Levkopoulos [38] to the real RAM model. Finally, we detail some important
 1 implications of our two new algorithms in Section 6.

2 Preliminaries

We review some known definitions, structures, algorithms, and their relationships.

2.1 Delaunay Triangulations and Euclidean Minimum Spanning Trees

Given a set P of n points in the plane, an important and extensively studied structure is the *Delaunay triangulation* of P [3, 6, 24, 43, 47], denoted $\text{DT}(P)$. It can be defined as the dual graph of the Voronoi diagram, the triangulation that optimizes the smallest angle in any triangle, or in many other equivalent ways, and it has been proven to optimize many other different criteria [42].

The *Euclidean minimum spanning tree* of P , denoted $\text{emst}(P)$, is the tree of smallest total edge length that has the points of P as its vertices, and it is well known that the EMST is a subgraph of the DT [47, Theorem 7]. In the following, we will assume that all the pairwise distances in P are distinct (a general position assumption), which implies that $\text{emst}(P)$ is uniquely determined. Finally, we remind the reader that $\text{emst}(P)$, like every minimum spanning tree, has the following *cut property*: let $P = R \cup B$ a partition of P , and let r and b be the two points with $r \in R$ and $b \in B$ that minimize the distance $|rb|$. Then rb is an edge of $\text{emst}(P)$. Note that this is very similar to the bichromatic closest pair reduction mentioned in the introduction, but the cut property holds for any partition of P , whereas the bichromatic closest pair reduction requires a very specific decomposition of P into pairs of subsets (which is usually not a partition).

2.2 Quadrees—Compressed and c -Cluster

Let P be a planar point set. The *spread* of P is defined as the ratio between the largest and the smallest distance between any two distinct points in P . A *quadtrees* for P is a hierarchical decomposition of an axis-aligned bounding square for P into smaller axis-aligned *squares* [3, 28, 33, 45]. A *regular* quadtree is constructed by successively subdividing every square with at least two points into four congruent child squares. A node v of a quadtree is associated with (i) S_v , the square corresponding to v ; (ii) P_v , the points contained in S_v ; and (iii) B_v , the axis-aligned bounding square for P_v . S_v and B_v are stored explicitly at the node. We write $|S_v|$ and $|B_v|$ for the diameter of S_v and B_v , and c_v for the center of S_v . We will also use the shorthand $d(u, v) := d(S_u, S_v)$ to denote the shortest distance between any point in S_u and any point in S_v . Furthermore, we denote the parent of v by \bar{v} . Regular quadtrees can have unbounded depth (if P has unbounded spread so in order to give any theoretical guarantees the concept is usually refined. In the sequel, we use two such variants of quadtrees, namely *compressed* and *c -cluster* quadtrees, which we show are in fact equivalent.

A *compressed* quadtree is a quadtree in which we replace long paths of nodes with only one child by a single edge [4, 5, 8, 21]. It has size $O(|P|)$. Formally, given a large constant a , an a -compressed quadtree is a regular quadtree with additional *compressed* nodes.² A compressed node v has only one child \underline{v} with $|S_{\underline{v}}| \leq |S_v|/a$ and such that $S_v \setminus S_{\underline{v}}$ has no points from P . Figure 3(a) shows an example. Note that in our definition $S_{\underline{v}}$ need not be aligned with S_v , which would happen if we literally “compressed” a regular quadtree. This relaxed definition is necessary because existing algorithms for computing aligned compressed quadtrees use a more powerful model of computation than our real RAM/pointer machine (see Appendix A). In the usual applications of quadtrees, this

² Such nodes are often called *cluster*-nodes in the literature [4, 5, 8], but we prefer the term *compressed* to avoid confusion with *c -cluster* quadtrees defined below.

Fig. 3: (a) A compressed quadtree on a set of 15 points. (b) A c -cluster tree on the same point set. (c) In a c -cluster quadtree, the internal nodes of the c -cluster tree are replaced by quadtrees.

is acceptable. In fact, Har-Peled [33, Chapter 2] pointed out that some non-standard operation is inevitable if we require that the squares of the compressed quadtree are perfectly aligned. However, here we intend to derandomize algorithms that work on a traditional real RAM/pointer machine, so we prefer to stay in this model. This keeps our results comparable with the previous work.

Now let c be a large enough constant. A subset $U \subseteq P$ is a c -cluster if $U = P$ or $d(U, P \setminus U) \geq c|B_U|$, where B_U denotes the smallest axis-aligned bounding square for U , and $d(A, B)$ is the minimum distance between a point in A and a point in B [37, 38]. In other words, U is a c -cluster precisely if $\{U, P \setminus U\}$ is a $(1/c)$ -semi-separated pair [33, 50]. It is easily seen that the c -clusters for P form a laminar family, i.e., a set system in which any two sets A and B satisfy either $A \cap B = \emptyset$; $A \subseteq B$; or $B \subseteq A$. Thus, the c -clusters define a c -cluster tree T_c . Figure 3(b) shows an example. These trees are a very natural way to tackle point sets of unbounded spread, and they have linear size. However, they also may have high degree. To avoid this, a c -cluster tree T_c can be augmented by additional nodes, adding more structure to the parts of the point set that are not strongly clustered. This is done as follows. First, recall that a quadtree is called *balanced* if for every node u that is either a leaf or a compressed node, the square S_u is adjacent only to squares that are within a factor 2 of the size of S_u .[□] For each internal node u of T_c with set of children V , we build a balanced regular quadtree on a set of points containing one representative point from each node in V (the intuition being that such a cluster is so small and far from its neighbors, that we might as well treat it as a point). This quadtree has size $O(|V|)$ (Lemma 3.4), so we obtain a tree of constant degree and linear size, the c -cluster quadtree. Figure 3(c) shows an example. The sets P_v , S_v and B_v for the c -cluster quadtree are just as for regular and compressed quadtrees, where in P_v we expand the representative points appropriately. Note that it is possible that $S_v \not\subseteq P_v$, but the points of P_v can never be too far from S_v . In Section 3.1 we elaborate more on c -cluster quadtrees and their properties, and in Section 3.3, we prove that c -cluster quadtrees and compressed quadtrees are equivalent (Theorem 3.12).

[□] We remind the reader that in our terminology, a *compressed node* is the node whose square contains a much smaller quadtree, and not the root node of the smaller quadtree.

2.3 Well-Separated Pair Decompositions

For any two finite sets U and V , let $U \otimes V := \{\{u, v\} \mid u \in U, v \in V, u \neq v\}$. A *pair decomposition* \mathcal{P} for a planar[‡] n -point set P is a set of m pairs $\{\{U_1, V_1\}, \dots, \{U_m, V_m\}\}$, such that (i) for all $i = 1, \dots, m$, we have $U_i, V_i \subseteq P$ and $U_i \cap V_i = \emptyset$; and (ii) for any $\{p, q\} \in P \otimes P$, there is exactly one i with $\{p, q\} \in U_i \otimes V_i$. We call m the *size* of \mathcal{P} . Fix a constant $\varepsilon \in (0, 1)$, and let $\{U, V\} \in \mathcal{P}$. Denote by B_U, B_V the smallest axis-aligned squares containing U and V . We say that $\{U, V\}$ is ε -*well-separated* if $\max\{|B_U|, |B_V|\} \leq \varepsilon d(B_U, B_V)$, where $d(B_U, B_V)$ is the distance between B_U and B_V (i.e., the smallest distance between a point in B_U and a point in B_V). If $\{U, V\}$ is not ε -well-separated, we say it is ε -*ill-separated*. We call \mathcal{P} an ε -*well-separated pair decomposition* (ε -WSPD) if all its pairs are ε -well-separated [11, 12, 26, 33].

Now let T be a (compressed or c -cluster) quadtree for P . Given $\varepsilon > 0$, it is well known that T can be used to obtain an ε -WSPD for P in linear time [12, 33]. Since we will need some specific properties of such an ε -WSPD, we give pseudo-code for such an algorithm in Algorithm 1. We call this algorithm `wspd`, and denote its output on input T by `wspd(T)`. The correctness of the algorithm `wspd` is immediate, since it only outputs well-separated pairs, and the bounds on the running time and the size of `wspd(T)` follow from a well-known volume argument which we omit [8, 12, 13, 33].

Algorithm 1 Finding a well-separated pair decomposition.

1. Call `wspd(r)` on the root r of T .

`wspd(v)`

1. If v is a leaf, return \emptyset .
2. Return the union of `wspd(w)` and `wspd(\{w_1, w_2\})` for all children w and pairs of distinct children w_1, w_2 of v .

`wspd(\{u, v\})`

1. If S_u and S_v are ε -well-separated, return $\{u, v\}$.
 2. Otherwise, if $|S_u| \leq |S_v|$, return the union of `wspd(\{u, w\})` for all children w of v .
 3. Otherwise, return the union of `wspd(\{w, v\})` for all children w of u .
-

Theorem 2.1. *There is an algorithm `wspd`, that given a (compressed or c -cluster) quadtree T for a planar n -point set P , finds in time $O(n)$ a linear-size ε -WSPD for P , denoted `wspd(T)`. \square*

Note that the WSPD is not stored explicitly: we cannot afford to store all the pairs $\{U, V\}$, since their total size might be quadratic. Instead, `wspd(T)` contains pairs $\{u, v\}$, where u and v are nodes in T , and $\{u, v\}$ is used to represent the pair $\{P_u, P_v\}$.

Note that the algorithm computes the WSPD with respect to the squares S_v , instead of the bounding squares B_v . This makes no big difference, since for compressed quadtrees $B_v \subseteq S_v$, and for c -cluster quadtrees B_v can be outside S_v only for c -cluster nodes, resulting in a loss of at most

[‡] Although some of these notions extend naturally to higher dimensions, the focus of this paper is on the plane.

2 a factor $1 + 1/c$ in separation. Referring to the pseudo-code in Algorithm 1, we now prove three
3 observations. The first observation says that the size of the squares under consideration strictly
4 decreases throughout the algorithm.

5 **Observation 2.2.** *Let $\{u, v\}$ be a pair of distinct nodes of T . If $\text{wspd}(\{u, v\})$ is executed by wspd
6 run on T (in particular, if $\{u, v\} \in \text{wspd}(T)$), then $\max\{|S_u|, |S_v|\} \leq \min\{|S_{\bar{u}}|, |S_{\bar{v}}|\}$.*

7 *Proof.* We use induction on the depth of the call stack for $\text{wspd}(\{u, v\})$. Initially, u and v are
8 children of the same node, and the statement holds. Furthermore, assuming that $\text{wspd}(\{u, v\})$ is
9 called by $\text{wspd}(\{u, \bar{v}\})$ (and hence $|S_u| \leq |S_{\bar{v}}|$), we get $\max\{|S_u|, |S_v|\} \leq |S_{\bar{v}}| = \min\{|S_{\bar{u}}|, |S_{\bar{v}}|\}$,
10 where the last equation follows by induction. \square

11 The next observation states that the wspd -pairs reported by the algorithm are, in a sense, as
12 high in the tree as possible.

13 **Observation 2.3.** *If $\{u, v\} \in \text{wspd}(T)$, then \bar{u} and \bar{v} are ill-separated.*

14 *Proof.* If $\bar{u} = \bar{v}$, the claim is obvious. Otherwise, let us assume that $\text{wspd}(\{u, v\})$ was called
15 by $\text{wspd}(\{u, \bar{v}\})$. This means that $\{u, \bar{v}\}$ is ill-separated and $\max\{|S_u|, |S_{\bar{v}}|\} = |S_{\bar{v}}|$. Therefore,
16 $\max\{|S_{\bar{u}}|, |S_{\bar{v}}|\} \geq |S_{\bar{v}}| > \varepsilon d(u, \bar{v}) \geq \varepsilon d(\bar{u}, \bar{v})$, and $\{\bar{u}, \bar{v}\}$ is ill-separated. \square

17 The last claim shows that for each wspd -pair, we can find well-behaved boxes whose size is
18 comparable to the distance between the point sets. In the following, this will be a useful tool for
19 making volume arguments that bound the number of wspd -pairs to consider.

20 **Claim 2.4.** *Let $\{u, v\} \in \text{wspd}(T)$. Then there exist squares R_u and R_v such that (i) $S_u \subseteq R_u \subseteq S_{\bar{u}}$
21 and $S_v \subseteq R_v \subseteq S_{\bar{v}}$; (ii) $|R_u| = |R_v|$; and (iii) $|R_u|/2\varepsilon \leq d(R_u, R_v) \leq 2|R_u|/\varepsilon$.*

22 *Proof.* Suppose $\text{wspd}(\{u, v\})$ is called by $\text{wspd}(\{u, \bar{v}\})$, the other case is symmetric. Let us define
23 $r := \min\{\varepsilon d(u, v), |S_{\bar{v}}|\}$. By Observation 2.2, we have $|S_u|, |S_v| \leq |S_{\bar{v}}| \leq |S_{\bar{u}}|$. Since $\{u, v\}$ is
24 well-separated, we have $\varepsilon d(u, v) \geq \max\{|S_u|, |S_v|\}$. Hence, $|S_{\bar{u}}|, |S_{\bar{v}}| \geq r \geq |S_u|, |S_v|$, and we can
25 pick squares R_u and R_v of diameter r that fulfill (i). Now (ii) holds by construction, and it remains
26 to check (iii). First, note that $d(R_u, R_v) \geq d(u, v) - 2r \geq (1 - 2\varepsilon)d(u, v) \geq r/2\varepsilon$, for $\varepsilon \leq 1/4$. This
27 proves the lower bound. For the upper bound, observe that $\varepsilon d(u, v) \leq \varepsilon(d(u, \bar{v}) + |S_{\bar{v}}|) \leq (1 + \varepsilon)|S_{\bar{v}}|$,
28 because $\{u, \bar{v}\}$ is ill-separated. Thus, we have $\varepsilon d(u, v)/2 \leq r$, and $d(R_u, R_v) \leq d(u, v) \leq 2r/\varepsilon$, as
29 desired. \square

30 **3 More on Quadtrees**

31 In this section, we describe a few more properties of the c -cluster trees and c -cluster quadtrees
32 defined in Section 2.2, and we prove that they are equivalent to the more standard compressed
33 quadtrees (Theorem 3.12). Since most of the material is very technical, we encourage the impatient
34 reader to skip ahead to Section 4.

35 **3.1 c -Cluster Quadtrees**

36 Krznanic and Levcopoulos [37, Theorem 7] showed that a c -cluster tree can be computed in linear
1 time from a Delaunay triangulation.

2 **Theorem 3.1** (Krznaric-Levcopolous). *Let P be a planar n -point set. Given a constant $c \geq 1$ and*
3 *$DT(P)$, we can find a c -cluster tree T_c for P in $O(n)$ time and space on a pointer machine. \square*

4 Here, we will actually use a more relaxed notion of c -cluster trees: let c_1, c_2 be two constants
5 with $1 \leq c_1 \leq c_2$, and let P be a planar n -point set. A (c_1, c_2) -cluster tree $T_{(c_1, c_2)}$ is a rooted tree
6 in which each inner node has at least two children and which has n leaves, one for each point in P .
7 Each node $v \in T_{(c_1, c_2)}$ corresponds to a subset $P_v \subseteq P$ in the natural way. Every node v must fulfill
8 two properties: (i) if v is not the root, then $d(P_v, P \setminus P_v) \geq c_1 |B_{P_v}|$; and (ii) if P_v has a proper
9 subset $Q \subset P_v$ with $d(Q, P \setminus Q) \geq c_2 |B_Q|$, then there is a child w of v with $Q \subseteq P_w$. In other
10 words, each node of $T_{(c_1, c_2)}$ corresponds to a c_1 -cluster of P , and $T_{(c_1, c_2)}$ must have a node for every
11 c_2 -cluster of P . Thus, the original c -cluster tree is also a (c, c) -cluster tree. Our relaxed definition
12 allows for some flexibility in the construction of $T_{(c_1, c_2)}$ while providing the same benefits as the
13 original c -cluster tree. Thus, outside this section we will be slightly sloppy and not distinguish
14 between c -cluster trees and $(c, \Theta(c))$ -cluster trees.

15 As mentioned above, the tree $T_{(c_1, c_2)}$ is quite similar to a well-separated pair decomposition:
16 any two unrelated nodes in $T_{(c_1, c_2)}$ correspond to a $(1/c_1)$ -well-separated pair. However, $T_{(c_1, c_2)}$ has
17 the huge drawback that it may contain nodes of unbounded degree. For example, if the points in
18 P are arranged in a square grid, then $T_{(c_1, c_2)}$ consists of a single root with n children. Nonetheless,
19 $T_{(c_1, c_2)}$ is still useful, since it represents a decomposition of P into well-behaved pieces. As explained
20 above, the (c_1, c_2) -cluster quadtree T is obtained by augmenting $T_{(c_1, c_2)}$ with quadtree-like pieces
21 to replace the nodes with many children.

22 We will now prove some relevant properties of (c_1, c_2) -cluster quadtrees. For a node u of $T_{(c_1, c_2)}$,
23 let T_u^Q be the balanced regular quadtree on the representative points of u 's children. The *direct*
24 *neighbors* of a square S in T_u^Q are the 8 squares of size $|S|$ that surround S . First, we recall how
25 the balanced tree T_u^Q is obtained: we start with a regular (uncompressed) quadtree T' for the
26 representative points. While T' is not balanced, we take a leaf square S of T' that is adjacent to a
27 leaf square of size less than $|S|/2$ and we split S into four congruent child squares. The following
28 theorem is well known.

29 **Theorem 3.2** (Theorem 14.4 of [3]). *Let T' be a quadtree with m nodes. The above procedure*
30 *yields a balanced quadtree with $O(m)$ nodes, and it can be implemented to run in $O(m)$ time. \square*

31 Let v be a child of u in $T_{(c_1, c_2)}$. The properties of the balanced quadtree T_u^Q and the fact that
32 the children of u are mutually well-separated yield the following observation.

33 **Observation 3.3.** *If c_1 is large enough, at most four leaf squares of T_u^Q contain points from P_v .*

34 *Proof.* Let $d := |B_v|$ be the diameter of the bounding square for P_v . By definition, P_v is a c_1 -cluster,
35 so the distance from any point in P_v to any point in $P \setminus P_v$ is at least $c_1 d$. Suppose that S is a leaf
36 square of T_u^Q with $S \cap P_v \neq \emptyset$, and let \bar{S} be the parent of S .

37 There are two possible reasons for the creation of S : either S is part of the original regular
38 quadtree for the representative points, or S is generated during the balancing procedure. In the
39 former case, \bar{S} contains at least two representative points. Thus, since in \bar{S} there is a point from
40 P_v and a point from $P \setminus P_v$, we have $|S| \geq c_1 d/2$. In the latter case, \bar{S} must be a direct neighbor of
41 a square with at least two representative points (see [3, Proof of Theorem 14.4]). Therefore, since
42 \bar{S} contains a point from P_v and has a direct neighbor with a point from $P \setminus P_v$, the diameter of S
1 is at least $c_1 d/4$. Either way, we certainly have $|S| \geq c_1 d/4$.

2 Now if $c_1 \geq 8$, then $c_1 d/4 \geq 2d$, so the side length of every leaf square S that intersects P_v is
3 strictly larger than d . Thus, P_v can be covered by at most 4 such squares, and the claim follows. \square

4 To see that (c_1, c_2) -cluster quadtrees have linear size, we need a property that is (somewhat
5 implicitly) shown in [38, Section 4.3].

6 **Lemma 3.4.** *If u has m children v_1, v_2, \dots, v_m in T_c , then T_u^Q has $O(m)$ nodes.*

7 *Proof.* Note that the total number of nodes in T_u^Q is proportional to the number of squares that
8 contain at least two representative points. Indeed, the number of squares in a balanced regular
9 quadtree is proportional to the number of squares in the corresponding unbalanced regular quadtree
10 (Theorem 3.2), and in that tree the squares with at least two points correspond to the internal
11 nodes, each of which has exactly four children. Thus, it suffices to show that the number of squares
12 in T_u^Q with at least two representative points is $O(m)$.

13 Call a square S of T_u^Q *full* if S contains a representative point. A full square $S \in T_u^Q$ is called
14 *merged* if it has at least two full children. There are $O(m)$ merged squares, so we only need to bound
15 the number of non-merged full squares with at least two points. These squares can be charged to
16 the merged squares, using the following claim.

17 **Claim 3.5.** *There exists a constant β (depending on c_2) such that the following holds: for any full
18 square S with at least two representative points, one of the β closest ancestors of S in T_u^Q (possibly
19 S itself) is either merged or has a merged direct neighbor.*

20 *Proof.* Let S be a non-merged full square with at least two representative points. Since S intersects
21 more than one P_{v_i} , the definition of $T_{(c_1, c_2)}$ implies that the set $S \cap P_u$ is not a c_2 -cluster. Thus,
22 $P_u \setminus S$ contains a point at distance at most $c_2|S|$ from S . Hence, S has an ancestor S' in T_u^Q that
23 is at most $O(\log c_2)$ levels above S and that has a full direct neighbor $S'' \neq S'$ (note that T_u^Q is
24 balanced, so S'' actually belongs to T_u^Q).

25 We repeat the argument: since $(S' \cup S'') \cap P_u$ is not a c_2 -cluster, there is a point in $P_u \setminus (S' \cup S'')$
26 at distance at most $c_2|S' \cup S''| \leq 2c_2|S'|$ from $S' \cup S''$. Thus, if we go up $O(\log c_2)$ levels in T_u^Q , we
27 either encounter a common ancestor of S' and S'' , in which case we are done, or we have found a
28 set \mathcal{S} of three full squares of T_u^Q such that (i) one square in \mathcal{S} is an ancestor of S ; (ii) the squares
29 in \mathcal{S} have equal size; and (iii) the squares in \mathcal{S} form a (topologically) connected set.

30 We keep repeating the argument while going up the tree. In each step, if we do not encounter
31 a common ancestor of at least two squares in \mathcal{S} , we can add one more full square to \mathcal{S} . However,
32 as soon as we have five squares of equal size that form a connected set, at least two of them have a
33 common parent. Thus, the process stops after at most two more iterations. Furthermore, since \mathcal{S} is
34 connected, once at least two squares in \mathcal{S} have a common parent, the parents of the other squares
35 must be direct neighbors of that parent. Hence, we found an ancestor of S that is only a constant
36 number of levels above S and that is merged or has a merged direct neighbor, as desired. \square

37 Now we use Claim 3.5 to charge each non-merged full node with at least two representative
38 points to a merged node. Each merged node is charged at most $9 \cdot 4^\beta = O(1)$ times, and Lemma 3.4
39 follows. \square

40 The proof of Lemma 3.4 implies the following, slightly stronger claim: Recall that T_u^Q was
41 constructed by building a regular quadtree for the representative points for u 's children, followed
1 by a balancing step. Now, suppose that before the balancing step we subdivide each leaf that

Fig. 4: (a) A regular quadtree on a set of 8 points. (b) A slight shift of the base square may cause many new compressed nodes in the quadtree.

2 contains a representative point for a c -cluster C until it has size at most $\alpha d(C, P \setminus C)$, for some
 3 constant $\alpha > 0$ (if the leaf is smaller than $\alpha d(C, P \setminus C)$, we do nothing). Call the tree that results
 4 after the balancing step T_2 .

5 **Corollary 3.6.** *The tree T_2 has $O(m)$ nodes.*

6 *Proof.* We only need to worry about the additional squares created during the subdivision of the
 7 leaves. If we take such a square and go up at most $\log(1/\alpha)$ levels in the tree, we get a square with
 8 a direct neighbor that contains a point from another cluster. Now the argument from the proof of
 9 Lemma 3.4 applies and we can charge the additional squares to merged squares, as before. \square

10 3.2 Balancing and Shifting Compressed Quadtrees

11 In this section, we show that it is possible to “shift” a quadtree; that is, given a compressed quadtree
 12 on a set of points P with base square R , to compute another compressed quadtree on P with a
 13 base square that is similar to R , in linear time. The main difficulty lies in the fact that the clusters
 14 in the two quadtrees can be very different, as illustrated in Figure 4.

15 **Theorem 3.7.** *Suppose a is a sufficiently large constant and P a planar n -point set. Furthermore,
 16 let T be an a -compressed quadtree for P with base square R , and let S be a square with $S \supseteq P$ and
 17 $|S| = \Theta(|R|)$. Then we can construct in $O(m)$ time a balanced a -compressed quadtree T' for P with
 18 base square S and with $O(m)$ nodes.*

19 The idea is to construct T' in the traditional way through repeated subdivision of the base
 20 square S , while using the information provided by T in order to speed up the point location. We
 21 will use the terms T -square and T' -square to distinguish the squares in the two trees. During the
 22 subdivision process, we maintain the partial tree T' , and for each square S' of T' we keep track of
 23 the T -squares that have similar size as S' and that intersect S' (in an associated set). We call the
 24 leaves of the current partial tree the *frontier* of T' . In each step, we pick a frontier T' -square and
 25 split it, until we have reached a valid quadtree for P . We need to be careful in order to keep T'
 26 balanced and in order to deal with compressed nodes. The former problem is handled by starting a
 1 cascading split operation as soon as a single split makes T' unbalanced. For the latter problem, we

2 would like to treat the compressed children in the same way as the points in P , and handle them
3 later recursively. However, there is a problem: during the balancing procedure, it may happen that
4 a compressed child becomes too large for its parent square and should be part of the regular tree.
5 In order to deal with this, we must keep track of the compressed children in the associated sets of
6 the T' -squares. When we detect that a compressed child has become too large for its parent, we
7 treat it like a regular square. Once we are done, we recurse on the remaining compressed children.
8 Through a charging scheme, we can show that the overall work is linear in the size of T . The
9 following paragraphs describe the individual steps of the algorithm in more detail.

10 **Initialization and Data Structures.** We obtain from S a grid with squares of size in $(|R|/2, |R|]$,
11 either by repeatedly subdividing S , if $|S| > |R|$; or by repeatedly doubling S , if $|S| \leq |R|/2$. Since
12 $|S| = \Theta(|R|)$, this requires a constant number of steps. Then we determine the T' -squares S'_1, \dots, S'_k
13 of that grid that intersect R (note that $k \leq 9$). Our algorithm maintains the following data
14 structures: (i) a list L of *active* T' -squares; and (ii) for each T' -square S' a list $\text{as}(S')$ of *associated*
15 T -squares. We will maintain the invariant that $\text{as}(S')$ contains the smallest T -squares that have size
16 at least $|S'|$ and that intersect S' , as well as any compressed children that are contained in such a
17 T -square and that intersect S' . This invariant implies that each S' has $O(1)$ associated squares. We
18 call a T' -square S' *active* if $\text{as}(S')$ contains a T -square of size in $[|S'|, 2|S'|)$ or a compressed child of
19 size in $[|S'|/2^{2a}, |S'|)$. Initially, we set $L := \{S'_1, \dots, S'_k\}$ and $\text{as}(S'_1) = \text{as}(S'_2) = \dots = \text{as}(S'_k) = \{R\}$,
20 fulfilling the invariant.

21 **The Split Operation.** The basic operation of our algorithm is the *split*. A split takes a T' -
22 square S' and subdivides it into four children S'_1, \dots, S'_4 . Then it computes the associated sets
23 $\text{as}(S'_1), \dots, \text{as}(S'_4)$ as follows. For each $i = 1, \dots, 4$, we intersect S'_i with all T -squares in $\text{as}(S')$,
24 and we put those T -squares into $\text{as}(S'_i)$ that have non-empty intersection with S'_i . Then we replace
25 each T -square in $\text{as}(S')$ that is neither a leaf, nor a compressed node, nor a compressed child by
26 those of its children that have non-empty intersection with S'_i . Finally, we remove from $\text{as}(S'_i)$
27 those compressed nodes whose compressed children have size at least $|S'_i|$ and intersect S'_i . Having
28 determined $\text{as}(S'_i)$, we use it to check whether S'_i is active. If so, we add it to L . The split operation
29 maintains the invariant about the associated sets, and it takes constant time.

30 **Main Body and Point-Location.** We now describe the main body of our algorithm. It consists
31 of *phases*. In each phase, we remove a T' -square S' from L . We perform a split operation on S' as
32 described above. Then, we start the *balancing procedure*. For this, we check the four T' -squares in
33 the current frontier that are directly above, below, to the left and to the right of S' to see whether
34 any of them have size $2|S'|$. We put each such T' -square into a queue Q . Then, while Q is not
35 empty, we remove a square N' from Q and perform a split operation on it (note that this may
36 create new active squares). Furthermore, if N' is in L , we remove it from L . Finally, we consider
37 the T' -squares of the current frontier directly above, below, to the left and to the right of N' . If any
38 of them have size $2|N'|$ and are not in Q yet, we append them to Q and continue. The balancing
39 procedure, and hence the phase, ends once Q is empty.

40 We continue this process until L is empty. Next, we do *point-location*. Let S' be a T' -square
41 of the current frontier. Since L is empty, S' is associated with $O(1)$ T -squares, all of which are
42 either leaves or compressed nodes or compressed children in T . For each T -leaf that intersects S' ,
1 we determine whether it contains a point that lies in S' . In the end, we have a set of at most four

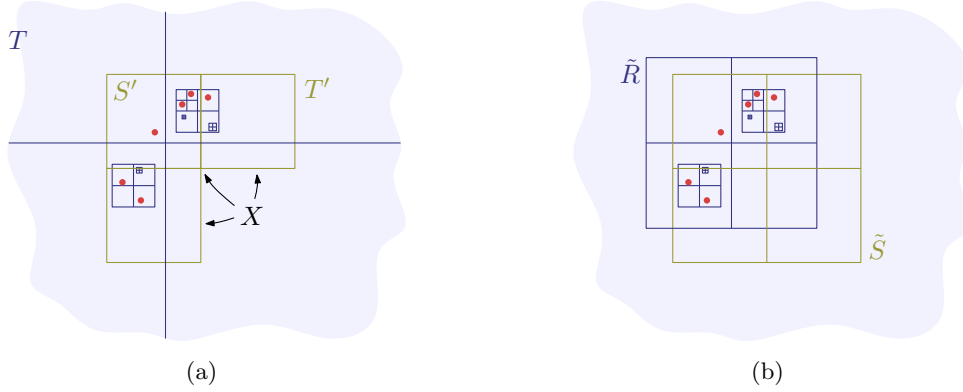

Fig. 5: (a) A frontier square S' of T' intersects several compressed children of T . We identify the list X of T' squares that intersect the same children. (b) To apply the shifting algorithm recursively, we choose base squares \tilde{R} and \tilde{S} aligned with T and T' .

2 points from P or compressed children of T that intersect S' , and we call this set the *secondary*
 3 associated set for S' , denoted by $\text{as}_2(S')$. We do this for every T' -square in the current frontier.

4 **The Secondary Stage.** Next, the goal is to build a small compressed quadtree for the secondary
 5 associated set of each square in the current frontier. Of course, the tree needs to remain balanced.
 6 For this, we start an operation that is similar to the main body of the algorithm. We call a T' -
 7 square S' *post-active* if $|\text{as}_2(S')| \geq 2$ and the smallest bounding square for the elements in $\text{as}_2(S')$
 8 has size larger than $|S'|/128a$. We put all the post-active squares into a list L_2 and we proceed
 9 as before: we repeatedly take a post-active square from L_2 , split it, and then perform a balancing
 10 procedure. Here, the splitting operation is as follows: given a square S' , we split it into four children
 11 S'_1, \dots, S'_4 . By comparing each child S'_i to each element in the secondary associated set $\text{as}_2(S')$, we
 12 determine the new secondary associated sets $\text{as}_2(S'_1), \dots, \text{as}_2(S'_4)$. We use these associated sets to
 13 check which children S'_i (if any) are post-active and add them to L_2 , if necessary. This splitting
 14 operation takes constant time. Again, it may happen that the balancing procedure creates new
 15 post-active squares. We repeat this procedure until L_2 is empty.

16 **Setting Up the Recursive Calls.** After the secondary stage, there are no more post-active squares,
 17 so for each square S' in the current frontier we have (i) $|\text{as}_2(S')| \leq 1$; or (ii) the smallest bounding
 18 square of $\text{as}_2(S')$ has size at most $|S'|/128a$. Below in Lemma 3.9 we will argue that if $\text{as}_2(S')$
 19 contains a single compressed child C , then C has size at most $|S'|/128a$. Thus, (ii) holds in any
 20 case. The goal now is to set up a recursive call of the algorithm to handle the remaining compressed
 21 children. Unfortunately, a compressed child may intersect several leaf T' -squares, so we need to be
 22 careful about choosing the base squares for the recursion.

23 Let S' be a square of the current frontier, and set $X := \{S'\}$. While there is a compressed
 24 child C in $\text{as}_2(X) := \bigcup_{S'' \in X} \text{as}_2(S'')$ that intersects the boundary of $S(X) := \bigcup_{S'' \in X} S''$, we add
 25 all the T' -squares of the current frontier that are intersected by C to X . Since T' is balanced,
 26 the i -th square $S^{(i)}$ that we add to X has size at most $2^i|S'|$ and hence the bounding square of
 27 $\text{as}_2(S^{(i)})$ has size at most $2^i|S'|/128a$. By construction, $\text{as}_2(S^{(i)})$ contains at least one element that
 1 intersects a square in the old X , so by induction we know that after i steps the set $\text{as}_2(X)$ has

2 a bounding square of size at most $2^{i+1}|S'|/128a$. It follows that the process stops after at most
3 three steps (i.e., when X has four elements), because after four steps we would have a bounding
4 square of size at most $2^5|S'|/128a \leq |S'|/4a$ that is intersected by five disjoint squares of size at
5 least $|S'|/2^4 = |S'|/16$ (since T' is balanced), which is impossible (for a large enough). Figure 5(a)
6 shows an example.

7 Now we put two base squares around $\text{as}_2(X)$: a square \tilde{R} that is aligned with T , and a square
8 \tilde{S} that is aligned with T' . For \tilde{R} , if $\text{as}_2(X)$ contains only one element, we just use the bounding
9 square of $\text{as}_2(X)$. If $|\text{as}_2(X)| \geq 2$, then the elements of $\text{as}_2(X)$ are separated by an edge or
10 a corner between leaf T -squares. Thus, we can pick a base square \tilde{R} for $\text{as}_2(X)$ such that (i)
11 $|\tilde{R}| \leq 2^6|S'|/128a = |S'|/2a$; (ii) \tilde{R} is aligned with T ; and (iii) the first split of \tilde{R} separates the
12 elements in $\text{as}_2(X)$. For \tilde{S} , if $|X| = 1$, we just use the bounding square for $\text{as}_2(X)$. If $|X| \geq 2$, the
13 squares in X must share a common edge or corner, and we can find a base square \tilde{S} such that (i) \tilde{S}
14 contains $\text{as}_2(X)$; (ii) the first split of \tilde{S} produces squares that are aligned with this edge or corner
15 of X ; and (iii) $|\tilde{S}| \leq 2^6|S'|/128a = |S'|/2a$. Figure 5(b) shows an example. We now construct
16 an a -compressed quadtree \tilde{T} with base square \tilde{R} for the elements of $\text{as}_2(X)$ in the obvious way.
17 (If $\text{as}_2(X)$ contains any compressed children, we reuse them as compressed children for \tilde{T} . This
18 may lead to a violation of the condition for compressed nodes at the first level of \tilde{T} . However, our
19 algorithm automatically treats large compressed children as active squares, so there is no problem.)
20 This takes constant time. We call the algorithm recursively to shift \tilde{T} to the new base square \tilde{S} .
21 Note that this leads to a valid a -compressed quadtree since either \tilde{S} is wholly contained in S' ; or
22 the first split of \tilde{S} produces squares that are wholly contained in the T' -leaf squares and have size
23 at most $|S'|/4a$, while each square that intersects \tilde{S} has size at least $|S'|/4$, as T' is balanced. We
24 repeat the procedure for every leaf T' -square whose secondary associated set we have not processed
25 yet.

26 **Analysis.** The resulting tree T' is a balanced a -compressed quadtree for P . It remains to prove
27 that the algorithm runs in linear time. The initialization stage needs $O(1)$ steps. Next, we consider
28 the main body of the algorithm. Since each split takes constant time, the total running time for
29 the main body is proportional to the number of splits. Recall that a T' -square S' is called *active*
30 if it is put into L , i.e., if $\text{as}(S')$ contains a T -square of size in $[|S'|, 2|S'|)$ or a compressed child of
31 size in $(|S'|/2^{2a}, |S'|]$. Since each T -square can cause only a constant number of T' -squares to be
32 active, the total number of active T' -squares is $O(m)$. Thus, we can use the following lemma to
33 conclude that the total number of splits in the main body of the algorithm is linear.

34 **Lemma 3.8.** *Every split in the main body of the algorithm can be charged to an active T' -square*
35 *such that each such square is charged a constant number of times.*

36 *Proof.* If we split an active square S' , we can trivially charge the split to S' . Hence, the critical
37 splits are the ones during the balancing procedure. By induction on the number of steps of the
38 balancing procedure, we see that if a square S' is split, there must be a square N' in the current
39 partial tree T' that is a direct neighbor of S' and that has an active descendant whose removal
40 from L triggered the balancing procedure.[□]

41 If N' has an active ancestor \tilde{N} that is at most five levels above N' in T' (possibly $\tilde{N} = N'$), we
42 charge the split of S' to \tilde{N} , and we are done. Otherwise, we know that $\text{as}(N')$ contains at least one
1 compressed child of size less than $|N'|/2^{2a}$ (otherwise, N' would not have an active descendant or

[□] Recall that a direct neighbor of S' is one of the eight squares of size $|S'|$ that surround S' .

would itself be active) and T -squares of size at least $64|N'|$ (otherwise, one of the five nodes above N' in T' would have been active). Now, before S' is split, there must have been a split on N' : otherwise the active descendant of N' that triggers the split on S' would not exist. Thus, we repeat the argument to show that N' has a direct neighbor N'' with an active descendant that triggers the split of S' . Note that $N'' \neq S'$, because the split on N' happens before the split on S' . If N'' has an active ancestor that is at most five levels higher up in T' (possibly N'' itself), we are done again. Otherwise, we repeat the argument again.

We claim that this process finishes after at most 16 steps. Indeed, suppose we find 17 squares $S' = N^{(0)}, N^{(1)}, N^{(2)}, \dots, N^{(17)}$ without stopping. We know that each $N^{(j)}$ is a direct neighbor of $N^{(j-1)}$ and that each $N^{(j)}$ is associated with a compressed child of size at most $|S'|/2^{2^a}$ and with T -squares of size at least $64|S'|$. Since the set $\bigcup_{j=0}^{16} N^{(j)}$ has diameter at most $17|S'|$, the set $\bigcup_{j=0}^{16} \text{as}(N^{(j)})$ contains at most four T -squares of size at least $64|S'|$. Now each compressed child in an associated set $\text{as}(N^{(j)})$ is the only child of one of these four large T -squares, so there are at most four of them. Furthermore, each such compressed child is intersected by at most four disjoint T -squares of size $|S'|$, so there can be at most 16 squares $N^{(j)}$, a contradiction. Hence, we can charge each split to an active square in the desired fashion, and the lemma follows. \square

Next, we analyze the running time of the secondary stage. Again, the running time is proportional to the number of splits, which is bounded by the following lemma.

Lemma 3.9. *Let S' be a frontier T' -square at the beginning of the secondary stage. Then after the secondary stage, the subtree rooted at S' has height at most $O(\log a)$.*

Proof. Below, we will argue that for every descendant S'' of S' , if $\text{as}_2(S'')$ contains a compressed child C , then $|C| \leq |S''|/2^a$. For now, suppose that this holds.

First, we claim that there are $O(\log a)$ splits to post-active descendants of S' . The secondary associated set $\text{as}_2(S')$ contains at most four elements, so $\text{as}_2(S')$ has at most 11 subsets with two or more elements. Fix such a subset \mathcal{A} . Then S' has at most $O(\log a)$ post-active descendants with secondary associated set \mathcal{A} . This is because each level of T' has at most two squares with secondary associated set \mathcal{A} , and the post-active squares with secondary associated set \mathcal{A} must have size between $|B(\mathcal{A})|/2$ and $128a|B(\mathcal{A})|$, where $B(\mathcal{A})$ denotes the smallest bounding square for the elements in \mathcal{A} . (Here we use our claim that the compressed children in the secondary associated set of each frontier T' -square S'' are much smaller than S'' .) There are only $O(\log a)$ such levels, so adding over all \mathcal{A} , we see that S' has at most $O(\log a)$ post-active descendants, implying the claim.

Each split creates at most one new level below S' , so there are only $O(\log a)$ new levels due to splits to post-active descendants of S' . Next, we bound the number of new levels that are created by splits during the balancing phases. Each balancing phase creates at most one new level below S' . Furthermore, by induction on the number of steps in the balancing phase, we see that the balancing phase was triggered by the split of a post-active square that is a descendant either of S' or of a direct neighbor of S' . At the beginning of the secondary stage, there are $O(1)$ T' -squares that are descendants of direct neighbors of S' (as T' is balanced). As we argued above, each of them has at most $O(\log a)$ post-active descendants. Thus, the balancing phases add at most $O(\log a)$ new levels below S' .

Finally, we need to justify the assumption that for any descendant S'' with a compressed child $C \in \text{as}_2(S'')$, we have $|C| \leq |S''|/2^a$. By construction, we have $|C| \leq |S'|/2^{2^a}$. Suppose that S' has a descendant S'' that violates this assumption. The square S'' was created through a split

2 in the secondary stage, and suppose that S'' is the first such square during the whole secondary
3 stage. This means that during all previous splits, the assumption holds, so by the argument above,
4 there are at most $O(\log a)$ levels below S' . This means that $|S''| \geq |S'|/a^{O(1)}$, so we would get
5 $|S'|/2^{2a} \geq |C| > |S''|/2^a > |S'|/2^{2a}$, a contradiction (for a large enough). Thus, no S'' can violate
6 the assumption, as desired. \square

7 The time to set up the recursion is constant for each square of the current frontier. From
8 Lemmas 3.8 and 3.9, we can conclude that the total time of the algorithm is $O(m)$, which also
9 implies that T' has $O(m)$ squares. This concludes the proof of Theorem 3.7.

10 **Special Cases.** We note two useful special cases of Theorem 3.7. The first one gives an analog of
11 Theorem 3.2 for compressed quadtrees.

12 **Corollary 3.10.** *Let T be a a -compressed quadtree with m nodes. There exists a balanced a -*
13 *compressed quadtree that contains T , has $O(m)$ nodes and can be constructed in $O(m)$ time.*

14 *Proof.* Let R be the base square of T . We apply Theorem 3.7 with $S = R$. \square

15 The second special case says that we can realign an uncompressed quadtree locally in any way
16 we want, as long as we are willing to relax the definition of quadtree slightly.[Ⓜ] Let P be a planar
17 point set. We call a quadtree for P λ -relaxed if it has at most λ points of P in each leaf, and is
18 otherwise a regular quadtree.

19 **Corollary 3.11.** *Let P be a planar point set and T a regular quadtree for P , with base square R .*
20 *Let S be another square with $S \supseteq P$ and $|S| = \Theta(|R|)$. Then we can build a 4-relaxed quadtree T'*
21 *for P with base square S in $O(|T|)$ time such that T' has $O(|T|)$ nodes.*

22 *Proof.* We apply Theorem 3.7 to T , but we stop the algorithm before the beginning of the secondary
23 stage. Since each secondary associated set for a leaf square has at most four elements, and since T
24 contains no compressed nodes, the resulting tree T' has the desired properties. \square

25 3.3 Equivalence of Compressed and c -Cluster Quadtrees

26 The goal of this section is to prove the following theorem.

27 **Theorem 3.12.** *Let P be a planar n -point set. Given a (c_1, c_2) -cluster quadtree on P , we can*
28 *compute in $O(n)$ time an $O(c_1)$ -compressed quadtree on P ; and given an a -compressed quadtree on*
29 *P , we can compute in $O(n)$ time an $(a^{1/5}, 2a^{1/5})$ -cluster quadtree on P .*

30 We present the proof of Theorem 3.12 in two lemmas.

31 **Lemma 3.13.** *Let P be a planar n -point set. Given a (c_1, c_2) -cluster quadtree T for P , we can*
1 *compute in linear time an $O(c_1)$ -compressed quadtree T' on P .*

[Ⓜ] We cannot get a non-relaxed (1-relaxed) uncompressed quadtree, since two points could be arbitrarily close to each other if they were separated by a boundary. However, we can always turn a λ -relaxed quadtree into a non-relaxed compressed quadtree in linear time again.

2 *Proof.* We construct the compressed quadtree in a top-down fashion, beginning from the root.
3 Suppose that we have constructed a partial compressed quadtree T' , and let q be the representative
4 point for a node u in the (c_1, c_2) -cluster tree $T_{(c_1, c_2)}$ that corresponds to T . We show how to expand
5 q in T' to the corresponding quadtree T_u^Q .

6 First, we add to T_u^Q a new root that is aligned with the old base square and larger by a
7 constant factor, such that the old base square does not touch any boundary of the new one. Next,
8 we determine by a search from q which leaf squares of T' intersect T_u^Q . By Observation 3.3, there
9 are at most four such leaves, so this step takes constant time. (Note that since we grow the base
10 square of each quadtree that we expand, it cannot happen that T_u^Q intersects the boundary of its
11 parent quadtree.) Next, we repeatedly split each leaf that intersects T_u^Q and that contains some
12 other point or compressed child until there are no more such leaves.

13 The proof of Observation 3.3 shows that every leaf square of T' that intersects T_u^Q has size at
14 least $c_1 d/4$, where d is the size of T_u^Q 's base square. If T_u^Q lies completely inside a leaf of T' , we add
15 T_u^Q as a compressed child to T' . If T_u^Q intersects more than one leaf square, we identify a square
16 at most twice the size of T_u^Q 's base square that is aligned appropriately with the relevant edges
17 of T , and apply Corollary 3.11 to shift T_u^Q to this new base square. This results in a valid $O(c_1)$
18 compressed quadtree in which q has been expanded. We repeat this process until all the quadtree
19 pieces of T have been integrated into a large compressed quadtree.

20 The total time for the top-down traversal and for the realignment procedures is linear. Fur-
21 thermore, Corollary 3.6 shows that the total work for splitting the leaves of T' is also linear, since
22 the points in the different clusters are $(1/c_1)$ -semi-separated. Hence, the total running time is
23 linear. \square

24 **Lemma 3.14.** *Let P be a planar n -point set, and T be an a -compressed quadtree for P . Then we*
25 *can compute in linear time a $(a^{1/5}, 2a^{1/5})$ -cluster quadtree for P .*

26 *Proof.* We use Corollary 3.10 to balance T , but without the recursive calls for the remaining cluster
27 nodes. This gives a balanced top-level quadtree T_{top} (possibly with some compressed children of T
28 now integrated in the tree), in which each leaf square is associated with at most four points from
29 P or compressed children of T . Furthermore, for each leaf square S of T_{top} , we have a bounding
30 square for the associated elements that is aligned with T and has size at most $|S|/a$.

31 We use T_{top} to identify a partial cluster quadtree, and we then recurse on the compressed
32 children. We say a square $S \in T_{\text{top}}$ is *full* if there is a leaf below S with a non-empty associated
33 set. Otherwise, S is *empty*. First, we consider the squares of T_{top} in top-down fashion and check
34 for each full square S which direct neighbors of S are empty (this can be done in constant time
35 since T is balanced). If S has at most three full direct neighbors, and if all these full squares share
36 a common corner, we let U be a square that is aligned with S and contains the full squares (i.e.,
37 either $U = S$ or U is a square of size $2|S|$ that contains S and its full neighbors). Next, we consider
38 the squares of size $|U|$ in the $(4a^{1/5} + 1) \times (4a^{1/5} + 1)$ grid centered at U and check whether they
39 are all empty (again, since T is balanced, this takes constant time). If so, the points associated
40 with U define a $a^{1/5}$ -cluster. We put a representative point for the cluster into U , make a new
41 quadtree with root U , and remove U 's children from T_{top} . We continue until all the squares of T_{top}
42 have been traversed, and then we process all the new trees in a similar way, iterating if necessary.
43 After we are done, a part of the cluster quadtree has been created, and we need to consider the
1 compressed children to set up a recursion.

Fig. 6: (a) The set of possible directions between two unrelated nodes u and v . (b) The set of possible directions between well-separated pairs is small.

2 For this, we consider each non-empty leaf square S of the partial tree. Let B be the bounding
3 square of the associated elements of S . We know that $|B| \leq |S|/a$, so the disc D of radius $2|B|a^{1/5}$
4 centered at B intersects at most three other leaf squares. We check for each of these leaf squares
5 whether D intersects the bounding square of its associated elements. If so, we make a new bounding
6 square for the union of these elements and repeat. This can happen at most twice more, because in
7 each step the size of the bounding square increases by a factor of at most $a^{1/5}$. Hence, after three
8 steps we have a disk D of radius $O(|B|a^{4/5})$ that intersects four disjoint squares of size $\Omega(|B|a)$
9 that share a corner. Thus, D must be completely contained in those squares. This also implies
10 that this procedure yields a $a^{1/5}$ -cluster. For each such cluster, we create a representative point
11 and an appropriate base square for the child quadtree. Then, we process the cluster recursively. In
12 the end, we can prune the resulting compressed trees to remove unnecessary nodes.

13 By the proof of Corollary 3.10, and since we spend only constant additional time for each square,
14 this procedure takes linear time. Furthermore, as we argued above, we create only $a^{1/5}$ -clusters. If
15 $Q \subset P$ is a $2a^{1/5}$ -cluster, then Q is either contained in at most four leaf squares of T_{top} that share
16 a corner or the bounding square B_Q intersects at most four squares of T_{top} of size $\Theta(|B_Q|)$ such
17 that the surrounding $(4a^{1/5} + 1) \times (4a^{1/5} + 1)$ grid contains only empty squares. In either case, Q
18 (or a superset) is discovered. It follows that the result is a valid $(a^{1/5}, 2a^{1/5})$ -cluster quadtree. \square

19 4 From a c -Cluster Quadtree to the Delaunay Triangulation

20 We now come to the heart of the matter and show how to construct a DT from a WSPD. Let P be
21 a set of points, and T a compressed quadtree for P . Throughout this section, ε is a small enough
22 constant (say, $\varepsilon = \pi/400$), and k is a large enough constant (e.g., $k = 100$). Let u and v be two
23 *unrelated* nodes of T , i.e., neither node is an ancestor of the other. Let L_{uv} be the set of directed
24 lines that stab S_u before S_v . The set $\Phi_{uv} \subseteq [0, 2\pi)$ of directions for L_{uv} is an interval modulo 2π
25 whose extreme points correspond to the two diagonal bitangents of S_u and S_v , i.e., the two lines
26 that meet S_u and S_v in exactly one point each and have S_u and S_v to different sides. Figure 6(a)
27 illustrates this.

28 **Observation 4.1.** *Let u and v be two unrelated nodes of T , and let \underline{u} be a descendant of u and \underline{v}
29 be a descendant of v . Then $\Phi_{\underline{u}\underline{v}} \subseteq \Phi_{uv}$.*

1 *Proof.* This is immediate, because $S_{\underline{u}} \subseteq S_u$ and $S_{\underline{v}} \subseteq S_v$. \square

2 **Observation 4.2.** *If u and v are two nodes of T such that $\{u, v\}$ is ε -well-separated, then $|\Phi_{uv}| \leq$
3 8ε .*

4 *Proof.* Let $d := |c_u c_v|$, D_u be the disk around c_u with radius εd , and D_v the disk around c_v with
5 the same radius.[□] By well-separation, $S_u \subseteq D_u$ and $S_v \subseteq D_v$. Let β be the angle between the
6 diagonal bitangents of D_u and D_v . Then $|\Phi_{uv}| \leq \beta$, and $\beta = 2 \arcsin(\varepsilon d / \frac{1}{2}d) = 2 \arcsin(2\varepsilon) \leq 8\varepsilon$,
7 as claimed. Figure 6(b) illustrates this. □

8 For a number $\phi \in [0, 2\pi[$ we define $\Phi_\phi := \{\psi \bmod 2\pi \mid \psi \in [\phi - \varepsilon/2, \phi + \varepsilon/2]\}$, i.e., the set
9 of all directions that differ from ϕ by at most $\varepsilon/2$. We say that an ordered pair (u, v) of nodes
10 has direction ϕ if $\Phi_{uv} \cap \Phi_\phi \neq \emptyset$. We also say that a pair of points (p, q) has direction ϕ if the
11 corresponding pair in the WSPD has direction ϕ . The same definition also applies to an edge. For
12 a given point p in the plane, we define the ε -cone $\mathcal{C}_\phi(p)$ as the cone with apex p and opening angle
13 ε centered around the direction ϕ .

14 4.1 Constructing a Supergraph of the EMST

15 In the following, we abbreviate $\mathcal{P} := \text{wspd}(T)$. The goal of this section is to construct a graph H
16 with vertex set P and $O(n)$ edges, such that $\text{emst}(P) \subseteq H$. It is well known that if we take the
17 graph H' on P with edge set $E := \{e_{uv} \mid \{u, v\} \in \mathcal{P}\}$, where each e_{uv} connects the bichromatic
18 closest pair for P_u and P_v , then H' contains $\text{emst}(P)$ and has $O(n)$ edges [26]. However, as defined,
19 it is not clear how to find H' in linear time. There are several major obstacles. Firstly, even though
20 the tree T has $O(n)$ nodes, it could be that $\sum_{u \in T} |P_u| = \Omega(n^2)$. Secondly, even if the total size of
21 all P_u 's was $O(n)$, we still need to find bichromatic closest pairs for all *pairs* in \mathcal{P} . Thus, a large
22 set P_u might appear in many pairs of \mathcal{P} , making the total problem size superlinear. Thirdly, we
23 need to actually solve the bichromatic closest pair problems. A straightforward solution to find the
24 bichromatic closest pair for sets R and B with sizes r and b would take time $O((r+b) \log(\min(r, b)))$,
25 by computing the Voronoi diagram for the smaller set and locating all points from the other set in
26 it. We need to find a way to do it in linear time.

27 To address these problems, we actually construct a slightly larger graph H , by partitioning the
28 pairs in \mathcal{P} according to their direction. More precisely, let $Y = \{0, \varepsilon, 2\varepsilon, \dots, (l-1)\varepsilon\}$ be a set of l
29 numbers, where we assume that $l = 2\pi/\varepsilon$ is an integer. For every $\phi \in Y$, we construct a graph H_ϕ
30 with $O(n)$ edges and then let $H = \bigcup_{\phi \in Y} H_\phi$. Given $\phi \in Y$, the graph H_ϕ is constructed in three
31 steps:

- 32 1. For every node $u \in T$, select a subset $Z_u \subseteq P_u$, such that $\sum_{u \in T} |Z_u| = O(n)$, and such that
33 $\{\{p, q\} \mid p \in Z_u, q \in Z_v, \{u, v\} \in \mathcal{P}\}$ still contains all edges of $\text{emst}(P)$ with orientation ϕ .
34 This addresses the first problem by making the total set size linear.
- 35 2. Find a subset $\mathcal{P}' \subseteq \mathcal{P}$, such that each $u \in T$ appears in $O(1)$ pairs of \mathcal{P}' , and the set
36 $\{\{p, q\} \mid p \in Z_u, q \in Z_v, \{u, v\} \in \mathcal{P}'\}$ contains all edges of $\text{emst}(P)$ with orientation ϕ . In
37 particular, we choose for every node $u \in T$ a subset $\mathcal{P}_u \subseteq \mathcal{P}$ such that $\mathcal{P}' = \bigcup_{u \in T} \mathcal{P}_u$, each
38 pair in \mathcal{P}_u contains u , and $|\mathcal{P}_u| = O(1)$. This addresses the second problem by ensuring that
1 every set appears in $O(1)$ pairs.

□ Recall, c_u is the center point of B_u .

Fig. 7: (a) A node u in the quadtree, with $|P_u| = 8$. (b) The relevant wspd-pairs (in green) for the points in P_u with direction ϕ (up). There are also wspd-pairs between u and other nodes above and below it. (c) For $k = 1$, Z_u contains those $p \in P_u$ for which the lowest wspd-pair in the tree T' that involves p contains u . In other words, Z_u has the points that do not have a green edge in both directions in (b).

- 2 3. For every pair $\{u, v\} \in \mathcal{P}'$, we include in H_ϕ the edge pq such that $\{p, q\}$ is the closest pair in $Z_u \otimes Z_v$ (i.e., $\{p, q\} = \operatorname{argmin}_{\{p', q'\} \in Z_u \otimes Z_v} |p'q'|$). Here we actually solve all the bichromatic closest pair problems.

5 Clearly, H_ϕ has $O(n)$ edges, and we will show that H is indeed a supergraph of $\operatorname{emst}(P)$. Our strategy of subdividing the edges according to their orientation goes back to Yao, who used a similar scheme to find EMSTs in higher dimensions [51].

8 **Step 1: Finding the Z_u 's.** Recall that we fixed a direction $\phi \in Y$. Take the set $\mathcal{P}_\phi \subseteq \operatorname{wspd}(T)$ of pairs with direction ϕ . For a pair $\pi \in \mathcal{P}_\phi$, we write (u, v) for the tuple such that $\pi = \{u, v\}$ and c_u comes before c_v in direction ϕ , it is a *directed* pair in \mathcal{P}_ϕ . Call a node u of T *full* if either (i) u is the root; (ii) u is a non-empty leaf; or (iii) \mathcal{P}_ϕ has a directed pair (u, v) . Let T' be the tree obtained from T by connecting every full node to its closest full ancestor, and by removing the other nodes. We can compute T' in linear time through a post-order traversal. Now, for every leaf v of T' , put the point $p \in P_v$ into the sets Z_u , where u is one the k^{\boxtimes} closest ancestors of v in T' . Repeat this procedure, while changing property (iii) above so that \mathcal{P}_ϕ has a directed pair (v, u) . This takes linear time, and $\sum_{u \in T} |Z_u| = O(n)$. Intuitively, Z_u contains those points of P_u that are sufficiently on the outside of the point set in direction ϕ . Figure 7 shows an example. Variants of the following claim have appeared several times before [1, 51].

19 **Claim 4.3.** Let $p \in P$, and let $\mathcal{C}_\phi^+(p)$ denote the cone with apex p and opening angle 17ε centered around ϕ . Suppose that pq is an edge of $\operatorname{emst}(P)$ and $q \in \mathcal{C}_\phi^+(p)$. Then q is the nearest neighbor of p in $\mathcal{C}_\phi^+(p) \cap P$.

22 *Proof.* If pq is an edge of $\operatorname{emst}(P)$, then the lune L defined by p and q contains no point of P [3].[Ⓜ] Since the opening angle of $\mathcal{C}_\phi^+(p)$ is at most $\pi/3$, for ε small enough, the intersection of $\mathcal{C}_\phi^+(p)$ with L equals the intersection of $\mathcal{C}_\phi^+(p)$ with the disk around p of radius $|pq|$. Hence, q must be the nearest neighbor of p in $\mathcal{C}_\phi^+(p) \cap P$. \square

26 **Lemma 4.4.** Let pq be an edge of $\operatorname{emst}(P)$ with direction ϕ , and let $\{u, v\}$ be the corresponding wspd-pair. Then $\{p, q\} \in Z_u \otimes Z_v$.

[Ⓜ] Recall, k is a sufficiently large constant.

[Ⓝ] L is the intersection of two disks with radius $|pq|$, one centered at p , the other centered at q .

2 *Proof.* Let w be the leaf for p , and suppose for contradiction that $p \notin Z_u$, i.e., u is not among
3 the k closest ancestors of w in T' . This means there exists a sequence u_1, u_2, \dots, u_k, u of $k + 1$
4 distinct ancestors of w , such that each node is an ancestor of all previous nodes and such there are
5 well-separated pairs $\{u_1, v_1\}, \{u_2, v_2\}, \dots, \{u_k, v_k\} \in \mathcal{P}_\phi$.

6 Let $\mathcal{C}_\phi^+(p)$ be the cone with apex p and opening angle 17ε centered around ϕ . By Observation 4.2,
7 we have $S_v, S_{v_1}, \dots, S_{v_k} \subseteq \mathcal{C}_\phi^+(p)$. Furthermore, since $\{u, v\}$ is well-separated, $d(u, v) \geq |S_u|/\varepsilon$. Now
8 Claim 2.4 implies that there are squares R_{u_1}, R_{v_1} such that (i) $S_{u_1} \subseteq R_{u_1} \subseteq S_{u_2}$ and $S_{v_1} \subseteq R_{v_1}$;
9 (ii) $|R_{u_1}| = |R_{v_1}|$; and (iii) $d(R_{u_1}, R_{v_1}) \leq 2|R_{u_1}|/\varepsilon$. This means that

$$d(p, P_{v_1}) \leq 2(1 + 1/\varepsilon)|R_{u_1}| \leq 2(1 + 1/\varepsilon)|S_{u_2}| \leq 2(1 + 1/\varepsilon)|S_u|/2^{k-1},$$

10 where in the first inequality we bounded the distance between any point in R_{u_1} and any point in
11 R_{v_1} by the distance between the squares plus their diameter (since we do not know where the points
12 lie inside the squares). The second inequality comes from $R_{u_1} \subseteq S_{u_2}$ and the third inequality is
13 due to the fact that S_{u_2} lies at least $k - 1$ levels below S_u in T' .

14 Since $2(1 + 1/\varepsilon)/2^{k-1} < 1/\varepsilon$ for $k \geq 3$ and since $d(u, v) \geq |S_u|/\varepsilon$, this contradicts the fact
15 that q is the nearest neighbor of p inside $\mathcal{C}_\phi^+(p)$ (Claim 4.3). Thus, p must lie in Z_u . A symmetric
16 argument shows $q \in Z_v$. \square

17 **Step 2: Finding the \mathcal{P}_u 's.** For every node $u \in T$, we include in \mathcal{P}_u the k shortest pairs in direction
18 ϕ , i.e., the pairs $\{u, v\} \in \text{wspd}(T)$ such that (i) c_v is contained in the ε -cone $\mathcal{C}_\phi(c_u)$ with apex c_u
19 centered around direction ϕ ; and (ii) there are less than k pairs $\{u, v'\} \in \text{wspd}(T)$ that fulfill (i)
20 and have $|c_u c_{v'}| < |c_u c_v|$. Since k is constant, the \mathcal{P}_u 's can be constructed in total linear time.
21 Even though each \mathcal{P}_u contains a constant number of elements, a node might still appear in many
22 such sets, so we further prune the pairs: by examining the \mathcal{P}_u 's, determine for each $v \in T$ the
23 set $\mathcal{Q}_v = \{u \in T \mid v \in \mathcal{P}_u\}$. For each \mathcal{Q}_v , find the k closest neighbors (measured by the distance
24 between their center points) of v in \mathcal{Q}_v , and for all other \mathcal{P}_u 's remove the corresponding pairs $\{u, v\}$.
25 Now each node appears in only a constant number of pairs of $\mathcal{P}' = \bigcup_{u \in T} \mathcal{P}_u$.

26 **Lemma 4.5.** *Let pq be an edge of $\text{emst}(P)$ with orientation ϕ , and let $\{u, v\}$ be the corresponding*
27 *wspd-pair. Then $\{u, v\} \in \mathcal{P}_u$.*

28 *Proof.* We show that v is among the k closest neighbors of u in direction ϕ , a symmetric argument
29 shows that u is among the k closest neighbors of v in direction $-\phi$. We may assume that $|c_u c_v| = 1$.
30 Suppose that $\{u, v\}$ is not among the k shortest pairs in direction ϕ . Then there is a set W of k nodes
31 of T such that for all $w \in W$ we have (i) $c_w \in \mathcal{C}_\phi(c_u)$; (ii) $|c_u c_w| < 1$; and (iii) $\{u, w\} \in \text{wspd}(T)$.
32 By Claim 2.4, there exists for every $w \in W$ a pair of squares $R_u(w), R_w$ such that $S_u \subseteq R_u(w)$,
33 $S_w \subseteq R_w$ and $|R_u(w)| = |R_w| \leq 2\varepsilon d(R_u(w), R_w) \leq 2\varepsilon$.

34 Let $\mathcal{C}_\phi^+(p)$ be the cone with apex p and opening angle 17ε centered around ϕ . By Observation 4.2,
35 $S_w \subseteq \mathcal{C}_\phi^+(p)$ for all $w \in W$. Furthermore, every S_w contains a point at distance at most $1 + \varepsilon$ from p ,
36 because $|c_w p| \leq |c_w c_u| + |c_u p| \leq 1 + \varepsilon$. Also, by Claim 4.3, every S_w contains a point at distance at
37 least $|pq| \geq |c_u c_v| - |c_u p| - |q c_v| \geq 1 - 2\varepsilon$ from p . Thus, since $d(R_u(w), R_w) \leq 2|R_w|/\varepsilon$ by Claim 2.4
38 and $d(R_u(w), R_w) \geq 1 - 2\varepsilon - 2|R_w|$, we get $|R_w| \geq \varepsilon/8$, for ε small enough. However, this implies
39 that W has only a constant number of squares: all S_w (and hence all R_w) intersect the annular
40 segment A inside $\mathcal{C}_\phi^+(p)$ with inner radius $1 - 2\varepsilon$ and outer radius $1 + \varepsilon$ (see Figure 8). All $w \in W$
1 are unrelated, since they are paired with u in $\text{wspd}(T)$. Furthermore, the set A has diameter $O(\varepsilon)$.

Fig. 8: All squares R_w intersect the region A .

2 If $w \in W$ is a compressed child, then R_w is contained in the parent of w and intersects no other
 3 $S_{w'}$, for $w' \in W$. Otherwise, $|S_w| \geq |R_w|/2$. Thus, if we assign to each compressed child $w \in W$ the
 4 square R_w and to each other node $w \in W$ the square S_w , we get a collection of k disjoint squares
 5 that meet A and each have diameter $\Omega(\varepsilon)$. Since A has diameter $O(\varepsilon)$, there can be only a constant
 6 number of such squares, so choosing k large enough leads to a contradiction. \square

7 **Step 3: Finding the Nearest Neighbors.** Unlike in the previous steps, the algorithm for Step 3
 8 is a bit involved, so we switch the order and begin by showing correctness.

9 **Lemma 4.6.** Let pq be an edge of $\text{emst}(P)$ with direction ϕ and let $\{u, v\}$ be the corresponding
 10 *uspd-pair*. Then $\{p, q\}$ is the closest pair in $Z_u \otimes Z_v$.

11 *Proof.* By Lemma 4.4, we have $\{p, q\} \in Z_u \otimes Z_v$. Furthermore, the cut property of minimum
 12 spanning trees implies that $pq \in \text{emst}(Z_u \cup Z_v)$. Since $\{u, v\}$ is well-separated, we have

$$\max_{\{p', q'\} \in Z_u \otimes Z_u \cup Z_v \otimes Z_v} |p'q'| < \min_{\{p', q'\} \in Z_u \otimes Z_v} |p'q'|. \quad (1)$$

13 Now consider an execution of Kruskal's MST algorithm on $Z_u \cup Z_v$ [22, Chapter 23.2]. Let $\{p', q'\}$
 14 be the closest pair in $Z_u \otimes Z_v$. By (1), the algorithm considers $p'q'$ only after processing all edges
 15 in $Z_u \otimes Z_u \cup Z_v \otimes Z_v$. Hence, at that point the sets Z_u and Z_v are each contained in a connected
 16 component of the partial spanning tree, and $\text{emst}(Z_u \cup Z_v)$ can have at most one edge from $Z_u \otimes Z_v$.
 17 Hence, it follows that $\{p, q\} = \{p', q'\}$, as claimed. \square

18 We now describe the algorithm. For ease of exposition, we take $\phi = \pi/2$ (i.e., we assume
 19 that P is rotated so that ϕ points in the positive y -direction). Note that now the squares are
 20 not generally axis-aligned anymore, but this will be no problem. Given a point $p \in \mathbb{R}^2$, we define
 21 the four *directional cones* $C_{\leftarrow}(p), C_{\uparrow}(p), C_{\rightarrow}(p)$, and $C_{\downarrow}(p)$ as the leftward, upward, rightward and
 22 downward cones with apex p and opening angle $\pi/2$. The directional cones subdivide the plane
 23 into four disjoint sectors. We will also need the *extended* rightward cone $C_{\rightarrow}^+(p)$ with apex p and
 24 opening angle $\pi/2 + 16\varepsilon$.

25 **Claim 4.7.** Let (u, v) be a directed pair in \mathcal{P}_ϕ , and suppose that $\{p, q\}$ with $p \in P_u$ and $q \in P_v$ is
 26 the closest pair for (u, v) . Then $C_{\uparrow}(p) \cap P_u = \emptyset$ and $C_{\downarrow}(q) \cap P_v = \emptyset$.^[10]

27 *Proof.* We prove the claim for $C_{\downarrow}(q)$, the argument for $C_{\uparrow}(p)$ is symmetric. We may assume that
 1 $|pq| = 1$. By assumption, the unit disk D centered at p contains no points of P_v , so it suffices to

^[10] Recall that we set $\phi = \pi/2$, so \uparrow and \downarrow mean “in direction ϕ ” and “in direction $-\phi$ ”.

Fig. 9: The intersection points of D and the boundary of $\mathcal{C}_\downarrow(q)$ lie outside S_v , so $S_v \cap \mathcal{C}_\downarrow(q) \subseteq D$.

Fig. 10: (a) A node u with $|Z_u| = 5$, and the relevant part of the quadtree. (b) The graph Γ . Tree edges are black (going right). To avoid clutter, we just show two wspd edges (green, going left).

2 show that $\mathcal{C}_\downarrow(q) \cap S_v \subseteq D$. Since $\{u, v\} \in \mathcal{P}_\phi$ and by Observation 4.2, the direction of the line \overline{pq}
3 differs from ϕ by at most 17ε . Therefore, the intersections of the boundaries of $\mathcal{C}_\downarrow(q)$ and D have
4 distance at least $\sqrt{2} - O(\varepsilon)$ from q . However, the pair $\{u, v\}$ is well-separated, so all points in P_v
5 have distance at most ε from q , which implies the claim; see Figure 9. \square

6 Given a set Z_u for a node u of T , we define the *upper chain* of Z_u , $\text{UC}(Z_u)$ as follows: remove
7 from Z_u all points p such that $\mathcal{C}_\uparrow(p)$ contains a point from Z_u in its interior. Then sort Z_u by
8 x -coordinate and connect consecutive points by line segments. All segments of $\text{UC}(Z_u)$ have slopes
9 in $[-1, 1]$. Similarly, we define the *lower chain* of Z_u , $\text{LC}(Z_u)$, by requiring the cones $\mathcal{C}_\downarrow(p)$ for the
10 points in $\text{LC}(Z_u)$ to be empty. The goal now is to compute $\text{UC}(Z_u)$ and $\text{LC}(Z_u)$ for all nodes u .

11 Define a directed graph Γ as follows: we create two copies of each vertex u in T , called $\text{start}(u)$
12 and $\text{end}(u)$, and we add a directed edge from $\text{start}(u)$ to $\text{end}(u)$ for each such vertex. Furthermore,
13 we replace every edge uv of T (u being the parent of v) by two edges: one from $\text{start}(u)$ to
14 $\text{start}(v)$, and one from $\text{end}(v)$ to $\text{end}(u)$. We call these edges the *tree-edges*. Finally, for every
15 pair $\{u, v\} \in \text{wspd}(T)$, where S_v is wholly contained in the extended rightward cone $\mathcal{C}_\downarrow^+(c_u)$, we
16 create a directed edge from $\text{end}(u)$ to $\text{start}(v)$. These edges are called *wspd-edges*. Figure 10
17 shows a small example.

18 **Claim 4.8.** *The graph Γ is acyclic.*

19 *Proof.* Suppose C is a cycle in Γ . The tree-edges form an acyclic subgraph, so C has at least one
20 wspd-edge. Let e_1, e_2, \dots, e_z be the sequence of wspd-edges along C , and let v_1, \dots, v_z be such
21 that the endpoint of e_i is of the form $\text{start}(v_i)$. Finally, write $C = e_1 \rightarrow C_1 \rightarrow e_2 \rightarrow C_2 \rightarrow$
22 $\dots \rightarrow e_z \rightarrow C_z$, where C_i is the sequence of tree-edges between two consecutive wspd-edges. Each
1 C_i consists of a (possibly empty) sequence of $\text{start} - \text{start}$ edges, followed by one $\text{start} - \text{end}$

Fig. 11: (a) A set of points, and all edges with a slope in $[-1, 1]$. By Claim 4.9, these edges are all (possibly implicitly) present in Γ . (b) A possible ordering \leq_Γ of the points that respects Γ .

2 edge and a (possibly empty) sequence of **end** – **end** edges. Thus, the origin of the next wspd-edge
3 e_{i+1} is an **end**-node for an ancestor or a descendant of v_i in T . In either case, by the definition of
4 wspd-edges, it follows that the leftmost point of $S_{v_{i+1}}$ lies strictly to the right of the leftmost point
5 of S_{v_i} . Indeed, write $e_{i+1} = (u_{i+1}, v_{i+1})$. Then $S_{v_{i+1}}$ lies strictly to the right of $S_{u_{i+1}}$, because
6 $S_{v_{i+1}} \subseteq \mathcal{C}_{\rightarrow}^+(c_{u_{i+1}})$ and because $\{u_{i+1}, v_{i+1}\}$ is well-separated. If u_{i+1} is a descendant of v_i , then
7 $S_{u_{i+1}} \subseteq S_{v_i}$ and the leftmost point of $S_{u_{i+1}}$ cannot lie to the left of the leftmost point of S_{v_i} , which
8 implies the claim. If u_{i+1} is an ancestor of v_i , then all of $S_{v_{i+1}}$ is strictly to the right of S_{v_i} , and the
9 claim follows again. Thus, the leftmost point of $S_{v_{i+1}}$ lies strictly to the right of the leftmost point
10 of S_{v_i} and the leftmost point of S_{v_1} lies strictly to the right of the leftmost point in S_{v_z} , which is
11 absurd. \square

12 Let \leq_Γ be a topological ordering of the nodes of Γ .

13 **Claim 4.9.** Any pair (p, q) of points in Z_u with $p \leq_\Gamma q$ satisfies $q \notin \mathcal{C}_{\leftarrow}(p)$.

14 *Proof.* Suppose for the sake of contradiction that $q \in \mathcal{C}_{\leftarrow}(p)$. Let v, w be the descendants of u
15 such that $q \in P_v, p \in P_w$, and $\{v, w\} \in \text{wspd}(T)$. By Observation 4.2, S_w lies completely in the
16 extended rightward cone $\mathcal{C}_{\rightarrow}^+(c_v)$, so Γ has an edge from **end**(v) to **start**(w). Now the tree edges in
17 Γ require that the leaf with q comes before **end**(v) and the leaf with p comes after **start**(w), and
18 the claim follows. \square

19 Since all edges on $\text{UC}(Z_u)$ have slopes in $[-1, 1]$, we immediately have the following corollary.

20 **Corollary 4.10.** The ordering \leq_Γ respects the orders of $\text{UC}(Z_u)$ and $\text{LC}(Z_u)$.

21 For every node $u \in T$, let \leq_u be the order that \leq_Γ induces on the leaf nodes corresponding to
22 Z_u .

23 **Claim 4.11.** All the orderings \leq_u can be found in total time $O(n)$.

24 *Proof.* To find the orderings \leq_u , perform a topological sort on Γ , in linear time^[11] [22, Chapter 22.4].
25 With each node u of T store a list L_u , initially empty. We scan the nodes of Γ in order. Whenever
26 we see a leaf for a point $p \in P$, we append p to the at most $2k$ lists L_u for the nodes u with $p \in Z_u$.
27 The total running time is $O(n + \sum_{u \in T} |Z_u|) = O(n)$, and L_u is sorted according to \leq_u for each
1 $u \in T$. \square

^[11] Note that Γ has $O(n)$ edges, as $|\text{wspd}(T)| = O(n)$.

2 **Claim 4.12.** For any node $u \in T$, if Z_u is sorted according to \leq_u , we can find $\text{UC}(Z_u)$ and $\text{LC}(Z_u)$
3 in time $O(|Z_u|)$.

4 *Proof.* We can find $\text{UC}(Z_u)$ by a Graham-type pass through L_u . An example of such a list is
5 shown in Figure 11(b). That is, we scan L_u from left to right, maintaining a tentative upper
6 chain U , stored as a stack. Let r be the rightmost point of U . On scanning a new point p , we
7 distinguish cases depending in which of the four quadrants $\mathcal{C}_{\leftarrow}(r)$, $\mathcal{C}_{\uparrow}(r)$, $\mathcal{C}_{\rightarrow}(r)$, or $\mathcal{C}_{\downarrow}(r)$ it lies in.
8 By Claim 4.1, we know that $p \notin \mathcal{C}_{\leftarrow}(r)$. If $p \in \mathcal{C}_{\downarrow}(r)$, we discard p and continue to the next point
9 in L_u . If $p \in \mathcal{C}_{\uparrow}(r)$, we pop r from U and reassess p from the point of view of the new rightmost
10 point of U . If $p \in \mathcal{C}_{\rightarrow}(r)$, we push p onto U .

11 The algorithm takes $O(|Z_u|)$ time, because every point is pushed or popped from the stack
12 at most once and because it takes constant time to decide which point to push or pop. Now we
13 argue correctness. For this, we use induction in order to prove that after i steps, we have correctly
14 computed the upper chain for the first i points in L_u , $\text{UC}(L_i)$. This clearly holds for the first point.
15 Now consider the cases for the $(i+1)$ -th point p .

- 16 • If $p \in \mathcal{C}_{\downarrow}(r)$, then p is certainly not on the upper chain. Furthermore, $\mathcal{C}_{\downarrow}(p) \subseteq \mathcal{C}_{\downarrow}(r)$, so p
17 cannot conflict with any other point on $\text{UC}(L_i)$, so in this case $\text{UC}(L_{i+1}) = \text{UC}(L_i)$.
- 18 • If $p \in \mathcal{C}_{\uparrow}(r)$, then $\mathcal{C}_{\uparrow}(p) \subseteq \mathcal{C}_{\uparrow}(r)$ and p must be on $\text{UC}(L_{i+1})$. Furthermore, every point that
19 we remove from $\text{UC}(L_i)$ has p in its upper cone and cannot be on $\text{UC}(L_{i+1})$. Now let r' be
20 the first point of $\text{UC}(L_i)$ that is not popped. Since $\mathcal{C}_{\leftarrow}(r') \subseteq \mathcal{C}_{\leftarrow}(p)$ and since the remainder
21 of $\text{UC}(L_i)$ lies inside of $\mathcal{C}_{\leftarrow}(r')$, there are no conflicts between p and the points we have not
22 popped. Thus $\text{UC}(L_{i+1})$ is computed correctly.
- 23 • If $p \in \mathcal{C}_{\rightarrow}(r)$, then $\mathcal{C}_{\uparrow}(p) \subseteq \mathcal{C}_{\uparrow}(r) \cup \mathcal{C}_{\rightarrow}(r)$, and p is on $\text{UC}(L_{i+1})$, because $\mathcal{C}_{\rightarrow}(r)$ contains no
24 points from L_i . Furthermore, $\text{UC}(L_i)$ is contained in $\mathcal{C}_{\leftarrow}(p)$, so p conflicts with no point on
25 $\text{UC}(L_i)$ and the result is correct.

26 This finished the inductive step and the correctness proof. The lower chain is computed in an
27 analogous manner. \square

28 **Claim 4.13.** For any node $u \in T$ and any pair $\{u, v\}$ in \mathcal{P}_u , given $\text{UC}(Z_u)$ and $\text{LC}(Z_v)$, we can
29 find the closest pair in $Z_u \otimes Z_v$ in time $O(|Z_u| + |Z_v|)$.

30 *Proof.* Connect the endpoints of $\text{UC}(Z_u)$ and $\text{LC}(Z_v)$ to obtain a simple polygon (note that the two
31 new edges cannot intersect the chains, because $\{u, v\}$ has direction $\phi = \pi/2$, so by Observation 4.2
32 $\Phi_{uv} \subseteq [\pi/2 - 8\frac{1}{2}\varepsilon, \pi/2 + 8\frac{1}{2}\varepsilon]$ and all edges of the chains have slopes in $[-1, 1]$). Then use the
33 algorithm of Chin and Wang [20] to find the constrained DT of the polygon in time $O(|Z_u| + |Z_v|)$.
34 The closest pair will appear as an edge in this DT, and hence can be found in the claimed time.^[12] \square

35 **Lemma 4.14.** In total linear time, we can find for every $u \in T$ and for every pair $\{u, v\} \in \mathcal{P}_u$ the
1 closest pair in $Z_u \otimes Z_v$.

^[12] Actually, the resulting polygon is x -monotone, so the most difficult part of the algorithm by Chin and Wang [20], finding the visibility map of the polygon [16], becomes much easier [31]. The problem may allow a much more direct solution, but since we will later require Chin and Wang's algorithm in full generality, we do not pursue this direction.

2 *Proof.* By Claims 4.11, 4.12, 4.13, the time to find all the closest pairs is proportional to

$$O(n + \sum_{u \in T} \sum_{\{u,v\} \in \mathcal{P}_u} (|Z_u| + |Z_v|)) = O(n + \sum_{u \in T} |Z_u|) = O(n),$$

3 because every v appears in only a constant number of \mathcal{P}_u 's. □

4 **Putting it together.** We thus obtain the main result of this section.

5 **Theorem 4.15.** *Given a compressed quadtree T for P and $\text{wspd}(T)$, we can find a graph H with*
 6 *$O(n)$ edges such that H contains all edges of $\text{emst}(P)$. It takes $O(n)$ time to construct H .*

7 *Proof.* The fact that H contains the EMST follows from Lemmas 4.4, 4.5 and 4.6. The running
 8 time follows from the discussion at the beginning of Steps 1 and 2 and from Lemma 4.14. □

9 4.2 Extracting the EMST

10 We want to extract $\text{emst}(P)$, but no general-purpose deterministic linear time pointer machine
 11 algorithm for this problem is known: the fastest such algorithm whose running time can be analyzed
 12 needs $O(n\alpha(n))$ steps [17]. However, the special structure of the graph H and the c -cluster quadtree
 13 T make it possible to achieve linear time.

14 We know that H contains all EMST edges. Furthermore, by construction each edge of H
 15 corresponds to a wspd -pair. Thus, we can associate each edge e of H with two nodes u and v such
 16 that $\{u, v\}$ is the wspd -pair for the endpoints of e . The pruning operation in Step 2 of Section 4.1
 17 ensures that each node is associated with $O(1)$ edges of H , and we store a list of these edges at each
 18 node of T . Now we use Theorem 3.12 to convert our quadtree into a c -cluster quadtree T . During
 19 this conversion, we can preserve the information about which edges of H are associated with which
 20 nodes of T , because each old square overlaps with only a constant number of new squares of similar
 21 size. A special case are those edges that have an endpoint associated with a compressed child.
 22 During the conversion of Theorem 3.12, compressed children either become regular squares (during
 23 the balancing operation), or they correspond to c -clusters and are replaced by representative points
 24 in the parent tree. In the former case, we handle the compressed child just like any regular square,
 25 in the latter case, we associate e with the square that contains the representative point for the
 26 c -cluster.

27 Next, we would like ensure for each edge e of H that the associated squares in T have size
 28 between $\varepsilon|e|/2$ and $2\varepsilon|e|$, where $|e|$ denotes the length of e . For the endpoints that were associ-
 29 ated with regular squares in the original quadtree, such a square can be found by considering a
 30 constant number of ancestors and descendants in T , by Claim 2.4. If the associated square was a
 31 compressed child that has become a regular square, we may need to consider more than a constant
 32 number of ancestors, but each such ancestor is considered only a constant number of times, since
 33 the compressed child has a constant number of associated edges. If e has an endpoint that is now
 34 associated with a representative point, we may need to subdivide the square containing the rep-
 35 resentative point, but by Corollary 3.6 the total work is linear. Thus, in total linear time we can
 36 obtain a c -cluster tree T such that each square of T is associated with $O(1)$ edges of H and such
 37 that the two associated square of each edge e of H contain the endpoints of e and have size $\Theta(\varepsilon|e|)$.

38 By the cut property of minimum spanning trees, $\text{emst}(P)$ is connected within each c -cluster.
 39 Thus, we can process the clusters bottom-up, and we only need to find the EMST within a c -
 1 cluster given that the points in each child are already connected. Within this cluster, T is a regular

2 uncompressed quadtree, and we can use the structure of T to perform an appropriate variant of
 3 Borůvka's MST algorithm [7, 48] in linear time.

4 **Lemma 4.16.** *Let T' be a subtree of T corresponding to a c -cluster, and let E be the edges in H
 5 associated with T' . Then $\text{emst}(P) \cap E$ can be computed in time $O(|E| + |V(T')|)$.*

6 *Proof.* Let ℓ be the size of the root square of T' . Through a level order traversal of T' we group the
 7 squares in $V(T')$ by height into layers V_1, V_2, \dots, V_h (where V_1 is the bottommost layer, and V_h
 8 contains only the root). The squares in V_i have size $\ell/2^{h-i}$. As stated above, each square S has a
 9 constant number of associated edges in E that have one endpoint in S and length length between
 10 $|S|/2\varepsilon$ and $2|S|/\varepsilon$. To find the EMST, we subdivide the edges into sets E_i , where E_i contains all
 11 edges with length in $[\ell/(\varepsilon 2^{h-i}), \ell/(\varepsilon 2^{h-i-1})]$. Given the V_i , we can determine the sets E_i in total
 12 time $O(|E| + |V(T')|)$, as the edges for E_i are associated only with squares in $V_{i-\alpha}, V_{i-\alpha+1}, \dots,$
 13 $V_{i+\alpha}$, for some constant α . Note that every edge in E_i is crossed by $O(1)$ other edges in E_i , because
 14 all $e \in E_i$ have roughly the same length and because every pair of squares in V_i has only a constant
 15 number of associated edges in E_i .

16 Now we compute the EMST by processing the sets E_1, \dots, E_h in order. Here is how to process
 17 E_i . We consider the squares in V_i . Assume that we know for each square of V_i the connected
 18 component in the current partial EMST it meets (initially each c -cluster is its own component).
 19 By the cut property, every square S meets only one connected component, as S is much smaller
 20 than the edges in E_i . Eliminate all edges in E_i between squares in the same component, and
 21 remove duplicate edges between each two components, keeping only the shortest of these edges
 22 (this takes $O(|E_i|)$ time with appropriate pointer manipulation). Then find the shortest edge out
 23 of each component and add these edges to the partial EMST. Determine the new components
 24 and merge their associated edge sets. This sequence of steps is called a *Borůvka-phase*. Perform
 25 Borůvka-phases until E_i has no edges left.

26 By the crossing-number inequality [41, Theorem 4.3.1], the number of edges considered in each
 27 phase is proportional to the number r of components with an outgoing edge in that phase. Indeed,
 28 viewing each component as a supervertex, we have an embedding of a graph with r vertices and z
 29 edges such that there are $O(z)$ crossings (since every edge $e \in E_i$ is crossed by $O(1)$ other edges
 30 in E_i). Thus, the crossing number inequality yields $z^3/r^2 \leq \beta z$, for some constant $\beta > 0$, so
 31 $z = O(r)$. Since the number of components at least halves in each phase, and since initially there
 32 are at most $|V_i|$ components, the total time for E_i is $O(|E_i| + |V_i|)$. Finally, label each square in
 33 V_{i+1} with the component it meets and proceed with round $i + 1$. In total, processing T takes time
 34 $O(|V(T')| + |E|)$, as desired. \square

35 4.3 Finishing Up

36 We conclude:

37 **Theorem 4.17.** *Let P be a planar point set and T be a compressed quadtree or a c -cluster quadtree
 38 for P . Then $\text{DT}(P)$ can be computed in time $O(|P|)$.*

39 *Proof.* If T is a c -cluster quadtree, invoke Theorem 3.12 to convert it to a compressed quadtree.
 40 Then use Theorem 2.1 to obtain $\text{wspd}(T)$. Next, apply Theorem 4.15 to compute the supergraph H
 41 of $\text{emst}(P)$. After that, if necessary, convert T to a c -cluster quadtree for P via Theorem 3.12, and
 42 apply Lemma 4.16 to each c -cluster, in a bottom-up manner, to extract $\text{emst}(P)$. Finally, apply
 1 the algorithm by Chin and Wang [20] to find $\text{DT}(P)$. All this takes time $O(|P|)$, as claimed. \square

5 From Delaunay Triangulations to c -Cluster Quadtrees

For the second direction of our equivalence we need to show how to compute a c -cluster quadtree for P when given $DT(P)$. This was already done by Krznaric and Levcopolous [37, 38], but their algorithm works in a stronger model of computation which includes the floor function and allows access to data at the bit level. As argued in the introduction, we prefer the real RAM/pointer machine, so we need to do some work to adapt their algorithm to our computational model. In this section we describe how Krznaric and Levcopolous's algorithm can be modified to avoid bucketing and bit-twiddling techniques. The only difference is that in the resulting c -cluster quadtree the squares for the c -clusters are not perfectly aligned with the squares of the parent quadtree. In our setting, this does not matter. The goal of this section is to prove the following theorem.

Theorem 5.1. *Given $DT(P)$, we can compute a c -cluster quadtree for P in linear deterministic time on a pointer machine.*

In the following, we will refer to the paper by Krznaric and Levcopolous [38] as KL. Our description is meant to be self-contained; however, we refer the reader to KL for more intuition and a more elaborate description of the main ideas.

5.1 Terminology

We begin by recalling some terminology from KL.

- **neighborhood.** The *neighborhood* of a square S of a quadtree consists of the 25 squares of size $|S|$ concentric around S (including S); see Figure 12.
- **direct neighborhood.** The *direct neighborhood* of a square S consists of the 9 squares of size $|S|$ directly adjacent to S (including S); see Figure 12.
- **star of a square.** Let P be a planar point set, and let S be a square. The *star* of S , denoted by $\star(S)$, is the set of all edges e in $DT(P)$ such that (i) e has one endpoint inside S and one endpoint outside the neighborhood of S ; and (ii) $|e| \leq 16|S|$, where $|e|$ is the length of e .
- **dilation.** Let P be a planar point set, and G a connected plane graph with vertex set P . The *dilation* of P is the distortion between the shortest path metric in G and the Euclidean distance, i.e., the maximum ratio, over all pairs of distinct points $p, q \in P$, between the length of the shortest path in G from p to q , and $|pq|$. There are many families of planar graphs whose dilation is bounded by a constant [23]. In particular, for any planar point set P , the dilation of $DT(P)$ is bounded by $2\pi/(3\cos(\pi/6)) \leq 2.42$ [35].
- **orientation.** The *orientation* of a line segment e is the angle the line through e makes with the x -axis.

5.2 Preprocessing

By Theorem 3.1, we can obtain a c -cluster tree T_c for P in linear time, given $DT(P)$. Thus, we only need to construct the regular quadtrees T_u^Q for each node u in T_c . This is done by processing each node of T_c individually. First, however, we need to perform a preprocessing step in order to find for

Fig. 12: The neighborhood of a square S . The direct neighbors are shown in dark blue, the others in light blue.

2 each edge e of $\text{DT}(P)$ the node of T_c that is the least common ancestor of e 's endpoints. For every
 3 node $u \in T_c$, we define $\text{out}(u)$ as the set of edges in $\text{DT}(P)$ that have exactly one endpoint in P_u and
 4 both endpoints in $P_{\bar{u}}$. Clearly, every edge is contained in exactly two sets $\text{out}(u)$ and $\text{out}(v)$, where
 5 u and v are siblings in T_c . The following is a simple variant of a lemma from KL [38, Lemma 3].

6 **Lemma 5.2** (Krzrnaric-Levcopolous). *Let P be a planar n -point set. Given $\text{DT}(P)$ and a c -cluster*
 7 *tree T_c for P , the sets $\text{out}(u)$ for every node $u \in T_c$ can be found in overall $O(n)$ time and space*
 8 *on a pointer machine.*

9 *Proof.* KL show how to reduce the problem of determining the sets $\text{out}(u)$ to $O(n)$ off-line least-
 10 common ancestor (lca) queries in two appropriate trees. For the lca-queries, they invoke an al-
 11 gorithm by Harel and Tarjan [34] that requires the word RAM. However, since all lca-queries are
 12 known in advance (i.e., the queries are *off-line*), we may instead use an algorithm by Buchsbaum
 13 *et al.* [10, Theorem 6.1] which requires $O(n)$ time and space on a pointer machine. \square

14 5.3 Processing a Single Node of T_c

15 We now describe the preprocessing that is necessary on a single node u of T_c before the quadtree T_u^Q
 16 can be constructed. Let v_1, v_2, \dots, v_m be the children of u . For each child v_i , let $\delta_i := d(P_{v_i}, P_u \setminus P_{v_i})$.

17 **Claim 5.3.** *For $i = 1, \dots, m$, $\text{out}(v_i)$ contains an edge of length δ_i .*

18 *Proof.* If $\text{DT}(P)$ contains an edge e with an endpoint in P_{v_i} and with length δ_i , then e must be
 19 in $\text{out}(v_i)$, by the definition of a c -cluster. Since $\text{emst}(P)$ is a subgraph of $\text{DT}(P)$, it thus suffices
 20 to show that $\text{emst}(P)$ contains such an edge. Consider running Kruskal's MST algorithm on P .
 21 According to the definition of a c -cluster, by the time the algorithm considers the edge e that
 22 achieves δ_i , the partially constructed EMST contains exactly one connected component that has
 23 precisely the points in P_{v_i} . Therefore, $e \in \text{emst}(P)$, and the claim follows. \square

24 **Initialization.** By scanning the sets $\text{out}(v_i)$, we determine a child v_j with minimum δ_j (by Claim 5.3
 25 a shortest edge in $\text{out}(v_i)$ has length δ_i). We may assume that $j = 1$. Let S_1 be a square that
 26 contains P_{v_1} and that has side-length $\delta_1/8$. Let α be the smallest integer such that four squares of
 1 size $2^{\alpha-1}\delta_1/8$ cover all of P_u . Lemma 3.4 implies that $\alpha = O(m)$.

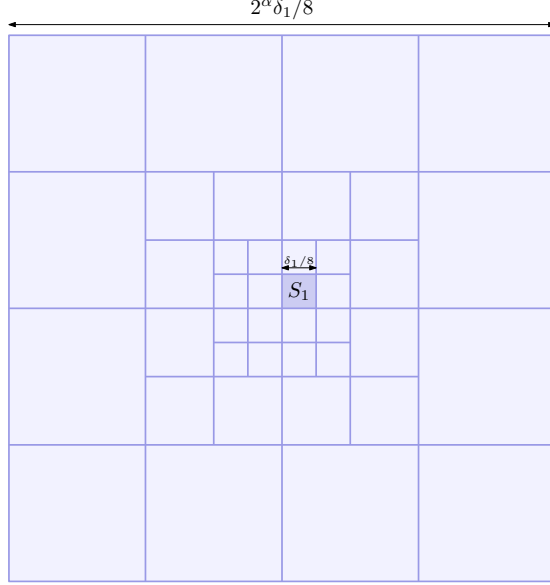

Fig. 13: The initial quadtree.

2 The goal is to compute T_u^Q , the balanced regular quadtree aligned at S_1 such that each P_{v_i}
 3 is contained in squares of size $\delta_i/8$. To begin, we use S_1 to initialize T_u^Q as the partial balanced
 4 quadtree T_u^Q shown in Figure 13. Every square S of T_u^Q stores the following fields:

- 5 • **parent**: a pointer to the parent square, **nil** for the root;
- 6 • **children**: pointers for the four children of S , **nil** for a leaf;
- 7 • **neighbors**: links to the four orthogonal neighbors of S in the quadtree T_u^Q with size $|S|$ (or
 8 size $2|S|$, if no smaller neighbor exists);

9 The fields **parent**, **children**, and **neighbors** are initialized for all the nodes in T_Q .

10 **Lemma 5.4.** *The total time for the initialization phase is $O(m + \sum_{i=1}^m |\text{out}(v_i)|)$.*

11 *Proof.* By Lemma 3.4, the initial size of T_u^Q is $O(m)$. All other operations consist of scanning the
 12 out-lists or are linear in the size of T_u^Q . □

13 5.4 Building the Tree T_u^Q

14 Now we build the tree T_u^Q by a traversing $DT(P)$ in a way reminiscent of Dijkstra’s algorithm [22].
 15 In their algorithm, KL make extensive use of the floor function in order to locate points inside their
 16 quadtree squares. The purpose of this section is to argue that this point location work can be done
 17 through local traversal of the quadtree, without the floor function. Refer to Algorithm 2. The heart
 18 of the algorithm is the procedure **explore**, which is initially called as **explore**($\{S_1\}, 2^{\alpha-1}\delta_1/8$). The
 19 procedure **explore** builds the tree T_u^Q level by level, beginning with the level of S_1 . At each point,
 20 it maintains a set **active** of all squares at the current level that contain a cluster that has already
 1 been processed. For each such square S , it calls a function **findStar**. This function returns all

Algorithm 2 Computing a c -cluster quadtree for the children of a c -cluster.

`explore(\mathcal{S} , maxsize)`

1. Set `active` := \mathcal{S} .
2. Set `newActive` := \emptyset .
3. Until the squares in `active` have size greater than `maxsize`:
 - (a) For every square S in `active` call the function `findStar(S)` to determine $\star(S)$. Append \bar{S} to `newActive`, if it is not present yet.
 - (b) For every edge $e \in \bigcup_{S \in \text{active}} \star(S)$, if e has an endpoint in an undiscovered cluster, call the function `newCluster(S, e)`, and append all the squares returned by this call to `newActive`.
 - (c) Set `active` := `newActive`.

`newCluster(S, e)`

1. Walk along e through the current T_u^Q to find the square S' of T_u^Q that contains the other endpoint of e . This tracing is done by following the appropriate `neighbor` pointers from S .
 2. Refine T_u^Q for the new cluster, and let S' be the set of leaf squares containing the newly discovered cluster.
 3. Call `explore(S' , size of squares in active)`. Afterwards, return the `active` squares from the recursive call.
-

2 edges of the Delaunay triangulation that have one endpoint in S and have length $\alpha|S|$, for a constant
 3 α . Using `findStar` we can new clusters whose distance from the active clusters is comparable to
 4 the size of the squares in the current level. We will say more about the implementation `findStar`
 5 below. For each new cluster, we call the procedure `newCluster` which adds more squares to T_u^Q
 6 to accommodate the new cluster and recursively explores the short edges out of this new cluster.
 7 After the recursive call has finished, we can continue the exploration of the tree at the current level.

8 We now give the details for the refinement in Step 2 of `newCluster`: Let v_j be the cluster that
 9 contains the other endpoint q of e (we can find v_j in constant time, since $e \in \text{out}(v_j)$, and since for
 10 each edge we store the two clusters whose `out`-lists contain it). Subdivide the current leaf square
 11 containing q (and possibly also its neighbors if they contain points from P_{v_j}) in quadtree-fashion
 12 until P_{v_j} is contained in squares of size $\delta_j/8$. Then balance the quadtree and update the `neighbor`
 13 pointers accordingly.

14 The algorithm is recursive, and at each point there exists a sequence $\mathcal{E}_1, \mathcal{E}_2, \dots, \mathcal{E}_z$ of instan-
 15 tiations (i.e., stack frames) of `explore`, where \mathcal{E}_{i+1} was invoked by \mathcal{E}_i . Each \mathcal{E}_i has a set `activei`
 16 of active squares, such that all squares in each `activei` have the same size, and such that the
 17 squares in `activei+1` are not larger than the squares in `activei`. We say that a square is active
 18 if it is contained in `activeT` := $\bigcup_i \text{active}_i$. The neighborhood of `activeT` is the union of the
 19 neighborhoods of all boxes in `active`. We maintain the following invariant:

1 **Invariant 5.5.** *At all times during the execution of `explore`, all undiscovered c -clusters lie outside*

2 the neighborhood of `activeT`.

3 **Claim 5.6.** *Invariant 5.5 is maintained by `explore`.*

4 *Proof.* The set `activeT` only changes in Steps 1 and 3c. The invariant is maintained in Step 1,
5 since the size of the squares in \mathcal{S} (i.e., $\delta_i/8$) is chosen such that their neighborhoods can contain
6 no point from any other cluster.

7 Let us now consider Step 3c. The set `newActive` contains two kinds of squares: (i) the parents
8 of squares processed in the current iteration of the main loop; and (ii) squares that were added to
9 `newActive` after a recursive call. We only need to focus on squares of type (i), since squares of
10 type (ii) are already added to `activeT` during the recursive call. Suppose that `activeT` contains
11 a square S whose neighborhood has a point $p \in P$ in an undiscovered cluster. Since $S \in \text{active}^T$,
12 there is a point $q \in P \cap \mathcal{S}$, and by the definition of neighborhood, we have $d(p, q) \leq 3|S|$. However,
13 since the dilation of $\text{DT}(P)$ is at most 2.5 [35], $\text{DT}(P)$ contains a path π of length at most $8|S|$
14 from p to q . Let p' be the last discovered point along π . The point p' lies in an active square S'
15 with $|S'| \geq |S|$, and the edge e leaving p' on π has length at most $8|S'|$. Therefore, $e \in \star(S'')$ for
16 a descendant S'' of S' , which contradicts the fact that p' is the last discovered point along π . \square

17 **Lemma 5.7.** *The total running time of `explore`, excluding the calls to `findStar`, is $O(m +$
18 $\sum_{i=1}^m |\text{out}(v_i)|)$.*

19 *Proof.* All squares appearing in `activeT` are ancestors of non-empty leaf squares in the final tree
20 T_u^Q . Therefore, by Lemma 3.4, the total number of iterations for the loop in Step 3a is $O(m)$.
21 Furthermore, $\star(S)$ contains only edges of length $\Theta(|S|)$, so every edge appears in only a constant
22 number of stars. It follows that the total size of the \star -lists, and hence the total number of iterations
23 of the loop in Step 3b is $O(\sum_{i=1}^m |\text{out}(v_i)|)$.

24 It remains to bound the time for tracing the edges and balancing the tree. Since T_u^Q is balanced
25 and since $\star(S)$ contains only edges of length $\Theta(|S|)$, the tracing along the `neighbor` pointers of
26 an edge takes constant time (since we traverse a constant number of boxes of size $\Theta(|S|)$). By
27 Invariant 5.5, the other endpoint of the edge is contained in a leaf square of the current T_u^Q of size
28 $\Theta(|S|)$. (This is because the quadtree is balanced and because the other endpoint of the edge lies
29 outside the neighborhood of the active squares.) Therefore, the time to build the balanced quadtree
30 for the new leaf squares containing the newly discovered cluster can be charged to the corresponding
31 nodes in the final T_u^Q , of which there are $O(m)$. Furthermore, note that by Invariant 5.5, balancing
32 the quadtree for the newly discovered leaf squares does not affect any descendants of the active
33 squares. \square

34 5.5 Implementing `findStar`

35 KL show how to exploit the geometric properties of the Delaunay triangulation in order to imple-
36 ment the function `findStar`, quickly. For this, they store two additional fields with each active
37 square, called `characteristic` and `shortcuts` [38, Section 6], and they explain how to maintain
38 these lists throughout the procedure. This part of the algorithm works on a real RAM/pointer
39 machine without any further modification, so we just state their result.

40 **Lemma 5.8.** *The total time for all calls to `findStar` and the maintenance of the required data*
41 *structures is $O(m + \sum_{i=1}^m |\text{out}(v_i)|)$.* \square

1 5.6 Putting Everything Together

2 We can now finally prove Theorem 5.1.

3 *Proof of Theorem 5.1.* First, we use Theorem 3.1 to find a c -cluster tree T_c for P in $O(n)$ time.
 4 Next, we use the algorithm from Section 5.2 to preprocess the tree. By Lemma 5.2, this also
 5 takes $O(n)$ time. Finally, we process each node of T_c using the algorithm from Section 5.3. By
 6 Lemmas 5.4, 5.7, and 5.8, this takes total time $\sum_j 1 + |\text{out}(v_j)|$, where the sum ranges over all
 7 the nodes of T_c . This sum is $O(n)$ because there are $O(n)$ nodes in T_c , and because every edge of
 8 $\text{DT}(P)$ appears in exactly two out -lists. Hence, the total running time is linear, as claimed. \square

9 6 Applications

10 As mentioned in the introduction, our result yields deterministic versions of several recent ran-
 11 domized algorithms related to DTs. Firstly, we can immediately derandomize an algorithm for
 12 hereditary DTs by Chazelle *et al.* [18, 19]:

13 **Corollary 6.1.** *Let P a planar n -point set, and let $S \subseteq P$. Given $\text{DT}(P)$, we can find $\text{DT}(S)$ in*
 14 *deterministic time $O(n)$ on a pointer machine.*

15 *Proof.* Use Theorem 5.1 to find a c -cluster quadtree T for P , remove the leaves for $P \setminus S$ from T and
 16 trim it appropriately.^[13] Finally, apply Theorem 4.17 to extract $\text{DT}(S)$ from T , in time $O(n)$. \square

17 Secondly, we obtain deterministic analogues of the algorithms by Buchin *et al.* [8] to preprocess
 18 imprecise point sets for faster DTs. For example, we can prove the following:

19 **Corollary 6.2.** *Let $\mathcal{R} = \langle R_1, R_2, \dots, R_n \rangle$ be a sequence of n β -fat planar regions so that no point*
 20 *in \mathbb{R}^2 meets more than k of them. We can preprocess \mathcal{R} in $O(n \log n)$ deterministic time into an*
 21 *$O(n)$ -size data structure so that given a sequence of n points $P = \langle p_1, p_2, \dots, p_n \rangle$ with $p_i \in R_i$ for*
 22 *all i , we can find $\text{DT}(P)$ in deterministic time $O(n \log(k/\beta))$ on a pointer machine.*

23 *Proof.* The method of Buchin *et al.* [8, Theorem 4.3 and Corollary 5.6] proceeds by computing
 24 a representative quadtree T for \mathcal{R} . Given P , the algorithm finds for every point in P the leaf
 25 square of T that contains it, and then uses this information to obtain a compressed quadtree T'
 26 for P in time $O(n \log(k/\beta))$. However, T' is *skewed* in the sense that not all its squares need to
 27 be perfectly aligned and that some squares can be cut off. However, the authors argue that even
 28 in this case $\text{wspd}(T)$ takes $O(n)$ time and yields a linear-size WSPD [8, Appendix B]. The main
 29 observation [8, Observation B.1] is that any (truncated) square S in T' is adjacent to at least
 30 one square whose area is at least a constant fraction of the area S would have without clipping.
 31 Since in skewed quadtrees the size of a node is at most half the size of its parent, the argument of
 32 Lemma 4.4 still applies. To see that Lemma 4.5 holds, we need to check that the volume argument
 33 goes through. For this, note that by the main observation of Buchin *et al.*, we can assign every
 34 square R_w (the notation is as in the proof of Lemma 4.5) to an adjacent square of comparable size
 35 at distance $O(\varepsilon)$ from A . Since every such square is charged by disjoint descendants from a constant
 36 number of neighbors, the volume argument still applies, and Lemma 4.5 holds. Lemma 4.14 only
 37 relies on well-separation and the combinatorial structure of T , and hence remains valid. Finally, in

^[13] Deleting $P \setminus S$ might create new c -clusters. However, since we are aiming for running time $O(n)$, we can apply Theorem 4.17 to a partly compressed quadtree that may contain long paths where every node has only one child.

1 order to apply Lemma 4.16, we need to turn T' into a c -cluster quadtree, which takes linear time
 2 by Theorem 3.12. Thus, the total running time is $O(n \log(k/\beta))$, as claimed. \square

3 Finally, Buchin and Mulzer [9] showed that for word RAMs, DTs are no harder than sorting.
 4 We can now do it deterministically. Let $\text{sort}(n)$ be the time to sort n integers on a w -bit word
 5 RAM. The best deterministic bound for $\text{sort}(n)$ is $O(n \log \log n)$ [32].^[14]

6 **Corollary 6.3.** *Let P be a planar n -point set given by w -bit integers, for some word-size $w \geq \log n$.
 7 We can find $\text{DT}(P)$ in deterministic time $O(\text{sort}(n))$ on a word RAM supporting the **shuffle**-
 8 operation.*^[15]

9 *Proof.* Buchin and Mulzer [9] show how to find a compressed quadtree T for P in time $O(\text{sort}(n))$,
 10 using the **shuffle**-operation. They actually do not find the squares of the quadtree, only the
 11 combinatorial structure of T and the bounding boxes B_v . It is easily seen that the algorithm **wspd**
 12 also works in this case.

13 To apply Lemma 4.4, we need to check that the sizes of the bounding boxes decrease geo-
 14 metrically down the tree. For this, consider a node $v \in T$ with associated point set P_v and the
 15 quadtree square S_v (i.e., the smallest aligned square of size 2^l such that the coordinates of all
 16 points in P_v share the first $w - l$ bits). Let B_v be the bounding box of P_v , and let l' be such that
 17 $2^{l'+1} \geq |B_v| \geq 2^{l'}$. Clearly, B_v meets at most nine aligned squares of size $2^{l'}$, arranged in a 3×3 grid.
 18 Hence, any descendant \underline{v} of v that is at least five levels below v must have $|B_{\underline{v}}| \leq |S_{\underline{v}}| \leq |B_v|/2$,
 19 since after at most four (compressed) quadtree divisions the squares for B_v have been separated.
 20 Thus, the proof of Lemma 4.4 goes through as before, if we choose k larger and consider every fifth
 21 node along the chain u_1, u_2, \dots, u_k, u .

22 Lemma 4.5 still holds, because every bounding box B_v is contained in a (possibly much larger)
 23 square S_v , so the volume argument applies. Also, Lemma 4.14 only relies on well-separatedness and
 24 the combinatorial structure of T , so we can find the graph H in linear time. After that, it takes
 25 $O(n)$ time to compute $\text{emst}(P)$, using the transdichotomous minimum spanning tree algorithm by
 26 Fredman and Willard [29]. \square

27 7 Conclusions

28 We strengthen the connections between proximity structures in the plane and sharpen several
 29 known results between them. Even though our results are optimal, the underlying algorithms are
 30 still quite subtle, and it may be of interest to see whether some of them can be simplified. It is
 31 also interesting to see whether systematic derandomization techniques, like ε -nets, can be useful to
 32 yield alternative deterministic algorithms for some of the problems considered here. Finally, some
 33 of the previous results also apply to higher dimensions, whereas we focus exclusively on the plane.
 34 Can we obtain analogous derandomizations for $d \geq 3$?

^[14] For specific ranges of w , we can do better. For example, if $w = O(\log n)$, radix sort shows that $\text{sort}(n) = O(n)$ [22].

^[15] For two w -bit words, $x = x_1 \dots x_w$ and $y = y_1 \dots y_w$, we define $\text{shuffle}(x, y)$ as the $2w$ -bit word $z = x_1 y_1 x_2 y_2 \dots x_w y_w$.

35 Acknowledgments

36 This work was initiated while the authors were visiting the Computational Geometry Lab at Car-
37 leton University. We would like to thank the group at Carleton and especially our hosts Jit Bose
1 and Pat Morin for their wonderful hospitality and for creating a great research environment. We
2 also would like to thank Kevin Buchin and Martin Nöllenburg for sharing their thoughts on this
3 problem with us. Work on this paper by M. Löffler has been supported by the Office of Naval
4 Research under MURI grant N00014-08-1-1015. Work by W. Mulzer has been supported in part by
5 NSF grant CCF-0634958, NSF CCF 083279, and a Wallace Memorial Fellowship in Engineering.

25 A Computational Models

26 Since our results concern different computational models, we use this appendix to describe them
27 in more detail. Our two models are the real RAM/pointer machine and the word RAM.

28 **The Real RAM/Pointer Machine.** The standard model in computational geometry is the *real*
29 *RAM*. Here, data is represented as an infinite sequence of storage cells. These cells can be of two
30 different types: they can store real numbers or integers. The model supports standard operations
31 on these numbers in constant time, including addition, multiplication, and elementary functions
32 like square-root. The *floor* function can be used to truncate a real number to an integer, but if
33 we were allowed to use it arbitrarily, the real RAM could solve PSPACE-complete problems in
34 polynomial time [46]. Therefore, we usually have only a restricted floor function at our disposal,
35 and in this paper it will be banned altogether.

36 The *pointer machine* [36] models the list processing capabilities of a computer and disallows
37 the use of constant time table lookup. The data structure is modeled as a directed graph G with

38 bounded out-degree. Each node in G represents a *record*, with a bounded number of pointers to
39 other records and a bounded number of (real or integer) data items. The algorithm can access data
1 only by following pointers from the inputs (and a bounded number of global entry records); random
2 access is not possible. The data can be manipulated through the usual real RAM operations (again,
3 we disallow the floor function).

4 **Word RAM.** The *word RAM* is essentially a real RAM without support for real numbers. How-
5 ever, on a real RAM, the integers are usually treated as atomic, whereas the word RAM allows for
6 powerful bit-manipulation tricks. More precisely, the word RAM represents the data as a sequence
7 of w -bit words, where $w \geq \log n$ (n being the problem size). Data can be accessed arbitrarily, and
8 standard operations, such as Boolean operations (**and**, **xor**, **shl**, \dots), addition, or multiplication
9 take constant time. There are many variants of the word RAM, depending on precisely which
10 instructions are supported in constant time. The general consensus seems to be that any function
11 in AC^0 is acceptable.^[16] However, it is always preferable to rely on a set of operations as small, and
12 as non-exotic, as possible. Note that multiplication is not in AC^0 [30]. Nevertheless, it is usually
13 included in the word RAM instruction set [29].

^[16] AC^0 is the class of all functions $f : \{0, 1\}^* \rightarrow \{0, 1\}^*$ that can be computed by a family of circuits $(C_n)_{n \in \mathbb{N}}$ with the following properties: (i) each C_n has n inputs; (ii) there exist constants a, b , such that C_n has at most an^b gates, for $n \in \mathbb{N}$; (iii) there is a constant d such that for all n the length of the longest path from an input to an output in C_n is at most d (i.e., the circuit family has bounded depth); (iv) each gate has an arbitrary number of incoming edges (i.e., the *fan-in* is unbounded).
