Assessment of rockfall risk along roads

P. Budetta

Department of Geotechnical Engineering, Section of Applied Geology, University of Naples "Federico II" piazzale Tecchio, 80, 80125 Napoli, Italy

Abstract. This paper contains a method for the analysis of rockfall risk along roads and motorways. The method is derived from the Rockfall Hazard Rating System (RHRS) developed by Pierson et al. (1990) at the Oregon State Highway Division. The RHRS provides a rational way to make informed decisions on where and how to spend construction funds. Exponential scoring functions are used to represent the increases, respectively, in hazard and in vulnerability that are reflected in the nine categories forming the classification. The resulting total score contains the essential elements regarding the evaluation of the degree of the exposition to the risk along roads.

In the modified method, the ratings for the categories "ditch effectiveness", "geologic characteristic", "volume of rockfall/block size", "climate and water circulation" and "rockfall history" have been rendered more easy and objective. The main modifications regard the introduction of Slope Mass Rating by Romana (1985, 1988, 1991) improving the estimate of the geologic characteristics, of the volume of the potentially unstable blocks and the underground water circulation. Other modifications regard the scoring for the categories "decision sight distance" and "road geometry". For these categories, the Italian National Council's standards (Consiglio Nazionale delle Ricerche - CNR) have been used (CNR, 1980). The method must be applied in both the traffic directions because the percentage of reduction in the decision sight distance greatly affects the results.

An application of the modified method to a 2 km long section of the Sorrentine road (no 145) in Southern Italy was developed. A high traffic intensity affects the entire section of the road and rockfalls periodically cause casualties, as well as a large amount of damage and traffic interruptions. The method was applied to seven cross sections of slopes adjacent to the Sorrentine road. For these slopes, the analysis shows that the risk is unacceptable and it should be reduced using urgent remedial works.

1 Introduction

Transportation corridors in many regions are often susceptible to landslides. Particularly, rockfalls constitute a major hazard in numerous rock cuts along roads in mountainous regions giving rise to casualties, as well as a large amount of damage and injuries. For these landslides, analysis of exposition to the risk is still a highly complex operation requiring an exact assessment of the hazard (triggering mechanisms and the run out parameters) and the vulnerability of vehicles on the roads along the foothills. Vulnerability depends on several factors connected to the type of vehicle/landslide deposit interaction considered. These factors include: the vehicle speed and length, the available decision sight distance, the traffic volume, the length of the landslide risk section of the route, the number of occupants in a vehicle, and the type of vehicle. Referring to routes, the "exposition to the risk" due to the landslides is given by the product of the annual probability of landsliding, the vehicle being spatially in the path of the event when it occurs, the vehicle being temporally in the path of the event when it occurs and one or more occupants of the vehicle being killed as a result (adapted from Morgan et al., 1992; Crosta and Frattini, 2000).

Harp and Noble (1993) developed an engineering rock classification system to evaluate seismic rockfall susceptibility based on previous method of quantitative description of discontinuities in rock masses from Barton (1978). Several authors proposed other methods for predicting the run outs paths of rockfalls (Paronuzzi, 1989; Pfeiffer and Bowen, 1989; Pfeiffer et al., 1991; Hoek, 1998; Guzzetti et al., 2002). This methods not only identify the paths of rockfalls, but the height of rock bounce and the velocity-all factors that are useful for evaluating rockfall risk to vehicles along roads.

Some statistical approaches have been proposed for calculating the "risk to life" (probability of death in the population exposed to the hazard for year: $P(D)$). Bunce et al. (1997) proposed a method based on binomial distribution to calculate the risk as a function of rockfall frequency regarding three identified combinations of interaction between

Table 1. Summary sheet of Rockfall Hazard Rating System (after Pierson et al., 1990).

Category		Rating criteria by score			
		Points 3	Points 9	Points 27	Points 81
	Slope height	7.5 m	15 m	22.5 m	> 30 m
	Ditch effectiveness	Good catchment	Moderate catchment	Limited catchment	No catchment
	Average vehicle risk (% of time)	25%	50%	75%	100%
	Decision sight distance (% of design value)	Adequate (100%)	Moderate (80%)	Limited (60%)	Very limited (40%)
	Roadway width (including paved shoulders)	13.20 m	10.80 m	8.40 m	6 m
Geologic characteristics — Case 1	Structural condition	Discontinuous joints, favorable orientation	Discontinuous joints, random orientation	Discontinuous joints, adverse orientation	Continuous joints, adverse orientation
	Friction	Rough, irregular	Undulating	Planar	Clay infilling or slickensided
Case 2	Structural condition	Few differential erosion features	Occasional erosion features	Many erosion features	Major erosion features
	Difference in erosion rates	Small	Moderate	Large	Extreme
	Block size	0.3 cm	0.6 m	0.9 m	1.20 m
	Volume of rockfall per event	2.3 m^3	4.6 m^3	6.9 m^3	9.2 m^3
	Climate and presence of water on slope	Low to moderate precipitation; no freezing periods; no water on slope water on slope	Moderate precipitation or short freezing periods or intermittent water on slope	High precipitation or long freezing periods or continual water on slope and long freezing periods	High precipitation and long freezing periods or continual
	Rockfall history	Few falls	Occasional falls	Many falls	Constant falls

the deposit and vehicles: (i) moving vehicle/falling rock, (ii) moving vehicle/fallen rock and (iii) stationary vehicle/falling rock. Within these categories the thickness and distribution of the deposit, the number of people in the vehicle, the speed and type of vehicle will affect the risk of interaction. Another statistical approach has been proposed by Hungr et al. (1999) using the slope of the magnitude – cumulative frequency curves for rockfalls along the main transportation corridors of south-western British Columbia. This procedure accounts only for accidents caused by a direct impact of the landslide deposit on a moving vehicle. For motorways, an approach that was considered to be compatible with the quality of input data available, is the "event tree" analysis (Whitman, 1984; Bunce et al., 1997; Hoek, 1998; Budetta, 2002; Budetta and Panico, 2002). In this analysis, an occurrence probability is assigned to each event in a sequence which could lead to a landslide fatality. The annual probability of death of at least one occupant of a vehicle $P(D)$ resulting from an impact on a landslide deposit is given by the product of the independent probabilities referred to each event in a sequence; e.g. land-

sliding probability in presence of triggering rainfall $P(r)$, vehicle breakdown probability $P(b)$ and significant impact probability resulting in a casualty for at least one occupant $P(d)$. For purposes of land planning and engineering mitigation, the compound probability $P(D)$ may be compared with the acceptable risk guidelines used for engineering construction projects and other human accidents (Guzzetti, 2000; Dai et al., 2002). The statistical approaches of risk analysis are very elaborate and require a large amount of data regarding the recurrence times of the landslides, which are not usually available. In fact, rockfalls that are not considered life threatening or significantly damaging usually go unreported. Furthermore, the documentation of activity is commonly poor for most roads and complete rockfall records are rare due to the low population density in landslide areas; the lack of reporting of small events by the companies that manage the roads; the personnel or monitoring costs that would be associated with data. As a result, a high level of sophisticated calculations is inadequate with the quality of the input information.
Fig. 1. Exponential scoring graph which can be used for estimates of the Rockfall Hazard Rating System (modified from Pierson et al., 1990).

2 The rockfall hazard rating system

In order to assess the exposition to the risk associated with rockfalls, and to prioritize budget allocations for maintenance and remediation works, the Oregon Department of Transportation (USA) has developed a classification scheme, designed specifically for motorway cuts, the Rockfall Hazard Rating System (Pierson et al., 1990; National Highway Institute, 1993; Scesi et al., 2001), to identify slopes which are dangerous and require urgent remedial work or further study. This is best summarized in Table 1. As illustrated in Fig. 1, an exponential scoring graph is used because it represents the increases, respectively, in hazard and in vulnerability that are reflected in the nine categories forming the classification. Because this method contains all the elements regarding the rockfall hazard (slope height, geologic character, volume of rockfall/block size, climate and presence of water on slope and rockfall history) and the vehicle vulnerability (ditch effectiveness, average vehicle risk, percent of decision sight distance, roadway width), the resulting total score assesses the degree of the exposition to the risk along roads.

The first step in this process is to make an inventory of the stability conditions of each slope so that they can be ranked according to their rockfall hazard. Then, the rockfall areas identified in the inventory are ranked by scoring the categories as shown in Table 1. Some categories require a subjective evaluation, whereas others can be directly measured and then scored. The rating criteria scores increase exponentially from 3 to 81 points and allow quickly to distinguish more dangerous sites.

3 The modified rockfall hazard rating system

Several studies in Southern Italy tested the applicability of RHRS and the method showed some critical aspects (Budetta and Panico, 2002). For example, some categories are described qualitatively and may lead to appraisals too much subjective and rough and, therefore, not sensitive enough.

This is particularly true for the categories: ditch effectiveness, geologic character, climate and presence of water on slope and rockfall history. So, only very expert users can draw advantage from this method. On the contrary, the method is easy to use for the purposes of land planning before studies of greater detail are performed.

The principal aim of this paper is to describe a modified methodology, pointing out limits and advantages, and to present the changes introduced to improve the aforesaid method. This is summarized in Table 2. In the modified method, the ratings for the categories ditch effectiveness, geologic characteristic, volume of rockfall/block size, climate and water circulation and rockfall history have been rendered easier and more objective. In succession, the categories of the modified method are shown.

3.1 Slope height

Category 1 represents the vertical height of the slope. Measurement is from the highest point from which boulder is expected. If boulders come from the natural slope above the cut, the cut height plus the additional slope height (vertical distance) are used. This category is the same as the original.

3.2 Ditch effectiveness

The effectiveness of a ditch is measured by its ability to prevent falling rock from reaching the road. In estimating the ditch effectiveness, the factors to be considered are: (i) slope height and angle; (ii) ditch width, depth, and shape. In the original method this ability is estimated qualitatively. As can be seen from Fig. 2, in the modified method references are to updates of Ritchie's ditch design chart (Ritchie, 1963) proposed by Fookes and Sweeny (1976) and Whiteside (1986). Furthermore, references are made to protection measures (barriers, rock catch fences, wire meshes, etc.) on slopes impending over roads.

3.3 Average vehicle risk

Category 3 represents the spatial probability of occurrence of a vehicle in the rockfall hazard zone. This average vehicle risk (AVR) is obtained by

$$AVR = (ADT \cdot SL \cdot 100\%)/PSP \qquad (1)$$

where ADT is the average traffic per day (vehicle/day); SL is the hazard zone length (km); and PSP is the posted speed limit (km/h).

A rating of 100% means that, on average, one vehicle can be expected to be within the hazard zone 100% of the examined time. A high AVR ($>100\%$) indicates that, at any particular time, more than one vehicle is present within the hazard zone (Pierson et al., 1990). This category is the same as the original.

Table 2. Summary sheet of the modified Rockfall Hazard Rating System.

Category	Rating criteria by score			
	Points 3	Points 9	Points 27	Points 81
Slope height	7.5 m	15 m	22.5 m	> 30 m
Ditch effectiveness	Good catchment: properly designed according to updates of Ritchie's ditch design chart + barriers	Moderate catchment: properly designed according to updates of Ritchie's ditch design chart	Limited catchment: wrongly designed	No catchment
Average vehicle risk (% of time)	25%	50%	75%	100%
Decision sight distance (% of design value)	Adequate (100%)	Moderate (80%)	Limited (60%)	Very limited (40%)
Roadway width	21.5 m	15.50 m	9.50 m	3.50 m
Slope Mass Rating (SMR)	80	40	27	20
Block size	30 cm	60 cm	90 cm	120 cm
Boulder volume	26 dm^3	0.21 m^3	0.73 m^3	1.74 m^3
Volume of rockfall per event	2.3 m^3	4.6 m^3	6.9 m^3	9.2 m^3
Annual rainfall and freezing periods	h=300 mm or no freezing periods	h=600 mm or short freezing periods	h=900 mm or long freezing periods	h=1200 mm or long freezing periods
Rockfall frequency	1 per 10 years	3 per year	6 per year	9 per year

Table 3. Tentative description of Slope Mass Rating (after Romana, 1991).

Class	V	IV	III	II	I
SMR	0–20	21–40	41–60	61–80	81–100
Description	Very bad	Bad	Normal	Good	Very good
Stability	Completely unstable	Unstable	Partially stable	Stable	Completely stable
Failures	Big planar or soil-like	Planar or big wedges	Some joints or many wedges	Some blocks	None

3.4 Percent of decision sight distance

Category 4 measures the percentage of reduction in the decision sight distance (DSD). DSD represents the length of road (in km) a driver needs in order to make a complex or instantaneous decision. The percent of decision sight distance ($PDSD$) is obtained by

$$PDSD = (ASD/DSD) \cdot 100\% \qquad (2)$$

where ASD is the actual sight distance (km).

Because DSD for USA roads is calculated differently as to Italian roads, in the modified method the Italian National Council standards have been used (Ferrari and Giannini, 1975; CNR, 1980). This is best summarized in Fig. 3. The decision sight distance is here considered as the distance along a roadway within which a 15 cm high stationary object is continuously visible from 1.10 m above the road (i.e. the height of a driver's eye on the road). DSD is critical when obstacles on the road are difficult to perceive, or when unexpected or unusual maneuvers are required. Furthermore, sight distance can change appreciably throughout a rockfall risk section. Motorway curves, along with obstructions such as rocky outcrops or roadside vegetation, can severely limit a driver's ability to notice landslide deposit. In addition, poor visibility during stormy weather may cause a reduction in sight distance. In the modified method, actual sight distances (ASD) in the two traffic directions should be evaluated because, normally, an object will be most obscured when it is located just beyond the sharpest part of a curve.
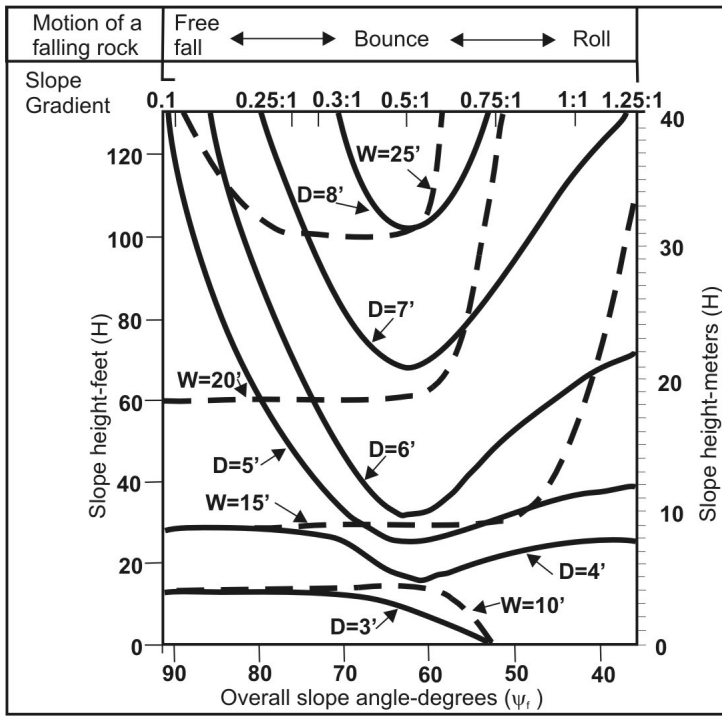

Fig. 2. Modified Ritchie's design chart to determine required width (W) and depth (D) of rock catch ditches in relation to height (H) and slope angle (ψ_f) of hillslope (after Whiteside, 1986).

3.5 Roadway width

The available maneuvering width, along a road to avoid a boulder is measured perpendicular to the motorway centerline from one edge of the pavement to the other and includes the shoulders. In the modified method, the Italian National Council standards have been used (road width classes). Therefore the roadway width doesn't include the shoulders that are not practical (CNR, 1980).

3.6 Geologic character

As can be seen from Table 1, the original method shows two cases of conditions that cause rockfalls. Case 1 includes slopes or cuts in which joints, bedding planes, or other discontinuities are the dominant structural features. Rock friction on a discontinuity is governed by the characteristics of the rock material as well as by the surface roughness and properties of any infilling. In Case 2 differential erosion or oversteepened slopes are the dominant conditions that control rockfalls. The different rates of erosion within a slope directly relate to the potential for a future landslide. For these two cases, the scoring criteria are qualitatively fixed and could cause doubts for users on which score to assign.

In the modified method, the Romana's Slope Mass Rating (SMR-Romana, 1985, 1988, 1991) for slope instability hazard evaluation is introduced. This is best summarized in Table 4. In order to assess the geologic characters that cause rockfalls some parameters are introduced to cover geomechanical features of discontinuities (attitude and shear

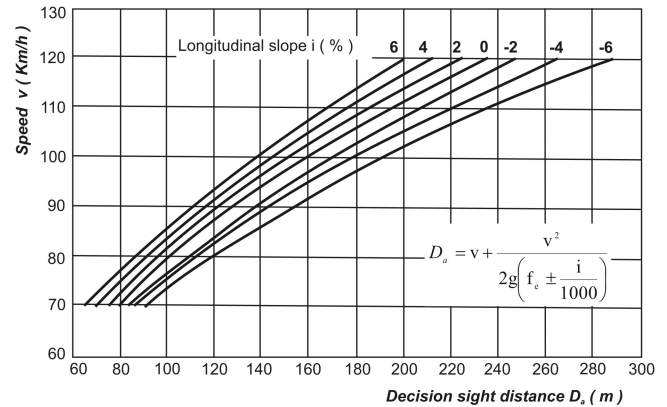

Fig. 3. Correlations between Decision Sight Distance (D_a) and Vehicle velocity (v) for different longitudinal slopes (i) (after CNR, 1980).

strength of joints), failure modes (planar, wedge and/or toppling) and cut excavation methods (natural slope, presplitting, smooth blasting and bulk blasting). SMR is obtained from RMR (Rock Mass Rating by Bieniawski, 1989) by subtracting a factorial adjustment factor depending on the joint – slope relationship and adding a factor depending on the method of excavation. The basic equation is

$$SMR = RMR - (F_1 \cdot F_2 \cdot F_3) \cdot F_4, \tag{3}$$

where F_1 is a factorial depending on parallelism between joints and slope face strikes; F_2 refers to joint dip angle in

Table 4. Exponential functions for the score computations in the modified RHRS method.

Category	Equation
Slope height (H)	$y=3^{H/7.5}$
Average vehicle risk (AVR)	$y=3^{AVR/25}$
Decision sight distance (%D_a)	$y=3^{(120-\%D_a)/20}$
Roadway width (L_c)	$y=3^{(27.5-L_c)/6}$
Slope mass rating (SMR)	$y=3^{80/SMR}$
Block size (D_b)	$y=3^{D_b/0.3}$
Volume of rockfall per event (V_{fall})	$y=3^{V_{\text{fall}}/2.3}$
Annual rainfall (h)	$y=3^{h/300}$
Rockfall frequency (f)	$y=3^{1+(0.334\cdot f)}$

the planar mode of failure, measuring the probability of joint shear strength; F_3 reflects the relationship between the slope face and joint dip; F_4 is an adjustment factor for the method of excavation.

Because weathering cannot be assessed with SMR, in certain degradable rock masses (like some marls, prevalently calcareous – marly flysch, etc.) the classification must be applied twice: for actual fresh and future weathered conditions (Romana, 1991). Another reason for which Romana's classification has been used in the modified method is to rate the joint spacing and groundwater conditions of rock masses outcropping on slopes. These parameters appear in other categories of RHRS.

3.7 Volume of rockfall/block size

In the original method there is no reference to which volume to employ, the block volume before the rockfall or that coming from the fallen boulder on the road. This specification is very important because the falling rock rarely keeps the original volume without breaking phenomena, after repeated rebounds on the slope. Consequently, in the modified method, the block volume (V_b) before rockfall has been evaluated statistically by means of the main joint sets spacing data ($S_1, S_2, \ldots, S_n$) affecting the rockmass. For rockmass with three joint sets (the most frequent case), V_b is given by

$$V_b = \frac{(S_1 \times S_2 \times S_3)}{(\sin\alpha \times \sin\beta \times \sin\gamma)}, \tag{4}$$

where α, β and γ are the angles between joint sets.

Then, the block size (D_b) is given by

$$D_b = \sqrt[3]{V_b}. \tag{5}$$

3.8 Climate and presence of water on slope

Intense rainfalls, freeze – thaw cycles and groundwater circulation contribute to instability and weathering of rockmass. In the RHRS method these causes are qualitatively estimated because thresholds of combined triggering parameters are difficult to assign.

In the modified method, the groundwater circulation is already considered in the Romana's Slope Mass Rating (SMR) and the slopes are rated according to mean values of annual rainfalls. Areas receiving less than 600 mm per year are moderate-precipitation areas. Areas receiving more than 1200 mm per year are considered high-precipitation areas. Finally, for freezing periods the original rating of the RHRS has been applied.

3.9 Rockfall history

In the modified method a careful data base of historical information is necessary for rating. As better rockfalls records are developed, more accurate conclusions for the rockfall potential can be made.

3.10 The exponential functions

The exponents of the equation $y=3^{f(x)}$ have been found by means of several attempts and they represent the expressions that best fit the data in Table 2. The complete mathematical description of the functions used to estimate the detailed rating eight categories scores (except ditch effectiveness) is shown in Table 4.

4 An application

The modified method was applied along a 2 km long section of the Sorrentine road (no 145) in Southern Italy. The geomorphologic and geomechanic settings of the studied area are shown in Figs. 4 and 5. High road cuts and natural outcrops above the road generate rockfalls along this road segment. As can be seen from Fig. 6, in recent years the area experienced several incidents including some fatalities as well as a large amount of damage and traffic interruptions. The studied area lies on the northern edge of the Sorrentine Peninsula which is a horst transversally oriented towards the Apennine mountain range. The Sorrentine Peninsula is made up of thick Mesozoic dolomitic limestone sequences on which Miocene flysch has been preserved in small structural depressions: Quaternary clastic deposits together with pyroclastics also crop out (Budetta et al., 1994).

Road cuts and natural slopes along the road belong to a very long and high (about 100 m) fault scarp striking N280° and dipping on average about 50°; vertical or overhanging slopes are not infrequent. Limestones and dolomitic limestones outcrop with bedding planes dipping about 15°−20° west-northwest. The rockmass is very fractured and there are many faults (at times with strike-slip lines) and joints most of which can be attributed to major
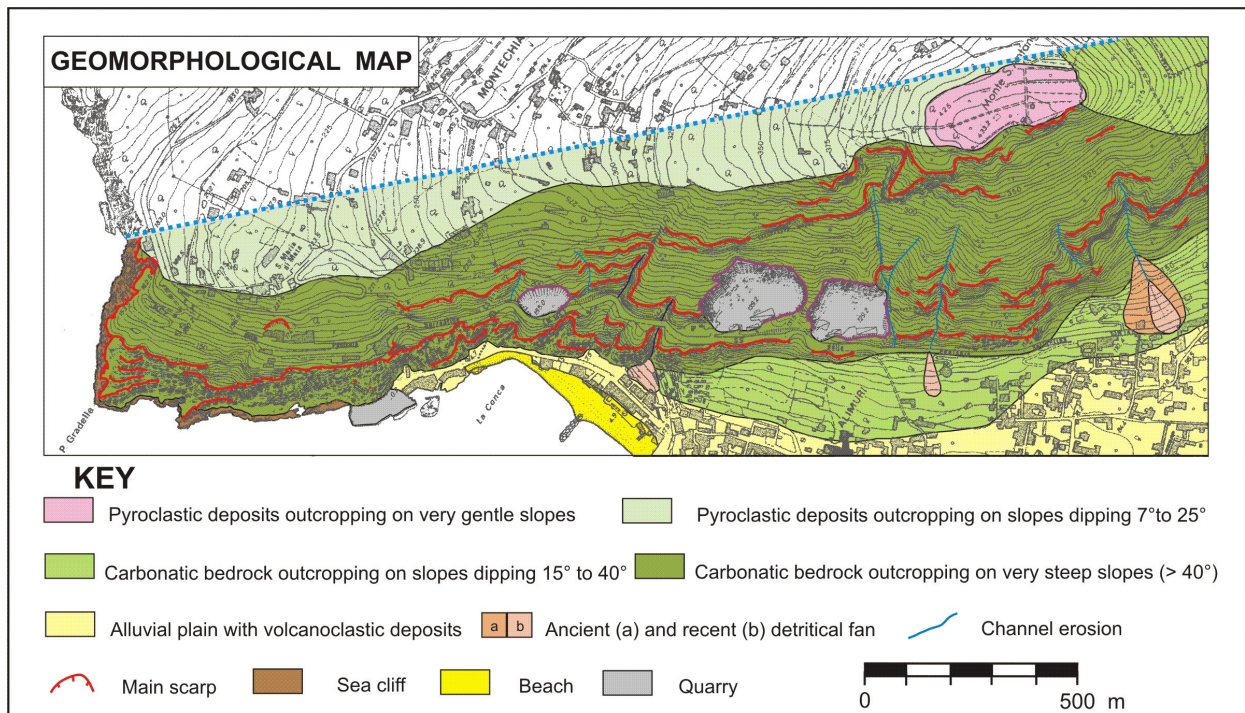

**Fig. 4.** Geomorphological map of the study area.

Fig. 5. Slope Mass Rating classes (after Romana, 1991) and cross section traces (red lines) for the modified RHRS method. Class I areas are absent.

joint sets with a smaller number randomly distributed. The geomorphologic structure is completed by the presence of several small interbedding caves. The Sorrentine road is located along the base of the foothills and was built during the first decades of the 19th century by the Bourbon Department of Bridges and Roads. The former historical information reported by the chief engineer of that period, refers to rockfalls that occurred in 1832 and 1838 during the road construction.

Other landslides occurred between Pozzano and Scrajo villages in 1842 and then in 1951 and 1958. Recent and well detailed rockfalls are referred to the second half of the last century. These are best summarized in Table 5. In the aftermath of each rockfall, the National Company which owns the road (Ente Nazionale per le Strade) carried out stabilization works designed to reduce the road vulnerability (e.g. anchorages, rock bolts, barriers and draped meshes). The studied
Fig. 6. Rockfalls of the 31 January 2001 event at Punta Orlando (after the "Il Mattino" newspaper of the 2 February 2001).

Fig. 7. Average daily traffic (ADT) recorded at Bivio Schito (km 11 and 800) during the given observation period (1995) (after Ente Nazionale per le Strade, 2001).

section of the road is without a ditch because there is a very little available space along the crossed fault scarp.

As can be seen from Fig. 7, a high traffic intensity affects the entire section of the road where the Posted Speed Limit (PSP) is 50 km/h. The average daily traffic was recorded between Meta di Sorrento and Bivio Schito, a distance of 10 km (Ente Nazionale per le Strade, 2001). The recorded traffic at Bivio Schito is representative of the transit in the studied section of the road because at Meta di Sorrento the data are affected by urban traffic. During the year, the average diurnal traffic is nearly constant (13 702 cars per day) but in nocturnal winter periods it is poor for the lack of tourism. About 80% of the traffic is represented by cars. The Sorrentine road is the only transportation corridor of this area and support a very high movement as well as touristic traffic.

As can be seen from Fig. 5, to establish the Slope Mass Rating (SMR) slopes with several degrees of instabilities have been registered and classified. Frequently the studied slopes are included in Romana's III and IV classes (Romana, 1988). Unstable or partially stable rock masses, with plane failures along many joints and big wedges, crop out along these slopes. Several analyses have been carried out on seven

cross sections including the road, by means of Hoek's rockfall program (Hoek, 1998) in order to reconstruct the trajectories of the boulders and estimate the most reliable kinematic parameters of the blocks governing the evolution of the phenomena. This is best summarized in Fig. 8. Using this program the maximum potential endpoint was statistically identified for each section by hypothesizing an initial plane sliding along the first straight line cell of the slope, i.e. mostly free fall, a main impact on the road followed by secondary rebounding and rolling until reaching its endpoint. As can be seen from Table 6, near the seven road sections the Decision Sight Distances (DSD) is very variable achieving a minimum value of about 10 m and a maximum of about 42 m. The block sizes (D_b) and volumes (V_b) which would fall on the road have been evaluated using the joint set spacing data affecting the rock masses, classified by means of the Romana's method. This is summarized in Table 7. Three points were assigned to the category "Rockfall frequency" on account of the recorded rockfalls on the road. Furthermore, 40 points were assigned to the category "Annual rainfall" because the studied area is included in a pluviometric region marked by annual rainfalls of about 1000 mm.

Finally, the rockfall areas impending the road were identified in the inventory and ranked by scoring the categories as shown in Table 8. These categories represent the significant elements of a rock slope that contribute to the overall risk. As can be seen from Fig. 9, the scores recorded for the seven cross sections were ranked in order to identify the most dangerous slopes, the total final scores range between 275 and 450. The analysis shows that there is an unacceptable risk and it must be reduced using urgent remedial works.

5 Concluding remarks

The difference in the total final scores between Sects. 1 and 2 (in the direction towards Meta di Sorrento) with respect to all remaining sections is mainly due to Decision Sight Distance (DSD). In fact, the considerable reduction in the per-

centage of DSD for the two traffic directions greatly affects the results. Also the categories Slope Height, Average Vehicle Risk and Volume of rockfall/Block size are more sensitive with respect to remaining categories.

In the RHRS's original method the slopes with scores lower than 300 are classified for remedial works with low urgency, whereas those higher than 500 need immediate stabilization measures. It would be better not to assign pre-established values, but in homogeneous areas for geological characteristics and traffic conditions to employ different remedial works whenever the relative scores have been assigned. Using a continuum of points allows flexibility in evaluating the relative impact of conditions that are variable by nature. It is to be remembered that this modified Rockfall Hazard Rating System is a preliminary tool for mapping the road risk assessment and then to allow more detailed

3 – (km 21 + 578)	0.36	0.71	13.46
4 – (km 21 + 618)	0.14	0.52	6.71
5 – (km 21 + 660)	0.52	0.80	18.72
6 – (km 21 + 720)	0.42	0.75	15.59
7 – (km 21 + 800)	0.09	0.45	5.20

investigations with geothecnical and geomechanical stability analyses in dangerous areas. Further applications in other geological environments are needed to better check its suitability for rockfall risk assessment.

Table 8. Application example of the modified RHRS method: (*) in the direction towards Naples; (°) in the direction towards Meta di Sorrento.

| No	Category	Value	Rating
1	Slope height	25 m	39
2	Ditch effectiveness	no catchment	81
3	Average vehicle risk	80%	34
4	Decision sight Distance	71% (*) 24% (°)	15 (*) 195 (°)
5	Roadway width	7 m	43
6	Slope Mass Rating (SMR)	50 (class III)	6
7	Block size	0.51 m	6
8	Annual rainfall	1005 mm	40
9	Rockfall frequency	1 per 10 years	3
